(54) Reference voltage generators

(57) A reference voltage generator comprises a differential amplifier with a negative feedback loop and having an input offset determining the output voltage, this offset being due to the difference in threshold voltages of two IGFETs T1, T2 resulting from the provision of differently doped semiconductor gate electrodes. The output of the amplifier is fed back to the inverting input either directly or via a potential divider and a reference voltage level (eg V_{ss} or V_{dd}) is connected to the non-inverting input. The output voltage is determined (relative to the reference voltage level) by the difference in threshold voltages of the input transistors this difference being substantially independent of temperature variations.

SPECIFICATION

Reference voltage generating device

5 The present invention specifically relates to a reference voltage generating device. Included within the present disclosure are other examples of reference voltage generating devices not within the scope of the present invention, applications of the generating devices, for example to a battery-checker, and methods of manufacturing semiconductor generating devices. 5

In generating reference voltages in various semi-conductor electronic circuits, it is necessary to utilize any physical quantity having the dimension of voltage. For such a physical quantity, only the forward voltage drop V_F or reverse breakdown voltage (Zener voltage) V_z of a PN-junction diode, the threshold voltage V_{th} of an insulated gate field-effect transistor (often represented by an IGFET or MOSFET), have been used. 10

These physical quantities do not provide voltage values which are fixed absolutely, but their voltage values are subject to fluctuations due to various factors. In order to make use of such physical quantities for 15 the reference voltage generating devices of various electronic circuits, attention must be paid to factors causing fluctuations of the voltage values to be obtained and to the allowable widths of such fluctuations. 15

With reference to the temperature characteristics of the physical quantities, the voltages V_F and V_{th} usually have a temperature-dependency of approximately 2 - 3 mV/ $^{\circ}$ C. The fluctuation of the reference voltage due to the temperature change attains a magnitude such that the application of these quantities in some uses must 20 be abandoned. 20

For example, when a battery checker to give an alarm when the voltage of a battery has lowered below a predetermined reference value is intended to be used in an electronic timepiece which employs a silver oxide battery having a nominal voltage of 1.5 V, whether the battery voltage is high or low needs to be judged with the boundary (detection level) or the detection reference value at about 1.4 V. 25

25 When a reference voltage generating device is to be constructed by exploiting the threshold voltage V_{th} of a MOSFET or the forward drop voltage V_F of a diode which is about 0.6 V, the detection level aimed at 1.4 V has a temperature-dependency of: 25

$$30 \quad \frac{1.4 \text{ V}}{0.6 \text{ V}} \times 2\text{--}3 \text{ mV } k^{-1} = 4.67\text{--}7.0 \text{ mV } k^{-1}. \quad 30$$

Accordingly, even when the practical operating temperature range is estimated as narrow as 0 $^{\circ}$ C to 50 $^{\circ}$ C, the detection level fluctuates by as much as 1.23 V to 1.57 V, and a practical battery checker is not achieved. 35

35 Also, the physical quantities have variations or deviations in the manufacture. For example, the threshold voltage V_{th} of a MOSFET has a variation of about +0.2V, which is greater than the temperature fluctuation. Thus, in the case where such a battery checker is in the form of an IC (integrated circuit) and exploiting the voltage V_{th} , not only external components and external connection pins (external connection terminals) for adjusting the reference voltage are required but also the labour of adjustment after the fabrication of the IC. 40

40 The lower voltage limit of the Zener voltage V_z is about 3 V, and it is impossible to generate a reference voltage to be used in a low voltage range of about 1 to 3 V. If the Zener voltage or the forward drop voltage of a diode are used as a reference voltage, a current of the order of several mA to several tens of mA needs to flow, which is inappropriate if it is necessary to minimize the power dissipation of the reference voltage generating device. 40

45 Therefore the conventional reference voltage generating devices exploiting the voltages V_{th} , V_F and V_z have not been suited to all the uses when the temperature characteristics, the variations or deviations in manufacture, the power dissipation, the voltage level etc. have been taken into account. For uses requiring very precise tolerances, it has often been necessary to relinquish either the practical use or the advantages of mass production. 45

50 Thus it is known that improvements in the conventional reference voltage generating devices are subject to physical limitation. 50

It is known that semiconductors have energy gaps E_g and various levels such as donor, acceptor and Fermi levels. However, no example has been proposed of a reference voltage generating device with note taken of the physics of semiconductors, especially the energy gap E_g and the Fermi level E_f . 55

55 According to the present invention there is provided a reference voltage generating device including: an operational amplifier including first and second insulating gate field-effect transistors (IGFETs) which have a difference of threshold voltages corresponding to a difference of Fermi levels of gate electrodes thereof, both said gate electrodes of said first and second IGFETs being made of an identical semiconductor material but having different conductivity types, a gate of said first IGFET being used as an inverting input of said operational amplifier whilst a gate of said second IGFET is used as a non-inverting input of said operational amplifier, an output terminal for delivering an output signal in response to a potential difference between said inverting and non-inverting inputs, and an input which is offset corresponding to said difference of threshold voltages; 60

a feedback connection means connected between said inverting input and output terminals of said operational amplifier for applying an output signal at said output terminal of the operational amplifier to said 65

inverting input terminal thereof; and
 a reference connection means for applying a reference potential to said non-inverting input terminal of the operational amplifier, whereby the reference voltage based on the difference of said threshold voltages of said first and second insulated gate field-effect transistors is derived between said output terminal of said operational amplifier and said reference potential.

The feedback connection means may include a controlling amplifier element having its control electrode which is coupled to said output terminal of said operational amplifier, its first output electrode, which is coupled to a power supply terminal, and its second output electrode which is coupled to said inverting input of said operational amplifier.

10 The second output electrode of said controlling amplifier element may be coupled to said inverting input of said operational amplifier through a voltage divider which is connected to said output electrode of said controlling amplifier element. Alternatively, the feedback connection means may include a voltage divider connected between said output terminal of said operational amplifier and said reference potential for applying a divided voltage of
 15 the output voltage appearing at said output terminal to said inverting input terminal. Preferably, said second insulated gate field-effect transistor is of the depletion type.
 The operational amplifier may include a third insulated gate field-effect transistor (IGFET) which is commonly coupled in series with drain-source paths of said first and second IGFETs, said third IGFET being driven by a timing signal, whereby during the conductive state of said third IGFET a stabilized output voltage
 20 is derived from said output terminal of said operational amplifier. The reference voltage generator device may additionally include:
 a first constant current source connected in series with the source-drain path of said first insulated gate field-effect transistor; and
 a second constant current source connected in series with the source-drain path of said second insulated
 25 gate field-effect transistor. The controlling amplifier element may be a fourth insulated gate field-effect transistor (IGFET). Alternatively the controlling amplifier element may be a bipolar transistor.
 The present invention will now be described, by way of example, with reference to the accompanying drawings, wherein:

The physics of semiconductors which begins with the crystalline structure of a semiconductor and which 45 develops into the energy band theory of a semiconductor and phenomena brought about in semiconductors by donor and acceptor impurities is explained in numerous texts.

It is, well known that semiconductors of different compositions have inherent energy gaps E_g and that the energy gap E_g expressed in eV has the dimension of voltage. However, there has not been any example of its use as a reference voltage source, from observations of the fact that the semiconductor has an inherent 50 energy gap E_g and that it exhibits a low temperature-dependence.

The present invention has been made by starting from the fundamentals of the physics of semiconductors. Therefore, the detailed description of this invention will begin with the principle features by firstly referring to the physics of semiconductors. Since the material properties of semiconductors are explained in detail in many texts they will now be briefly described with the aid of one of the texts, "Physics of Semiconductor

55 Devices" by S.M. SZE, published by John Wiley & Sons in 1969, especially Chapter 2 "Physics and Properties of Semiconductors" on pages 11 and 65.

There are various compositions of semiconductors. Among them, typical as semiconductors industrially utilized at present, are non-compound semiconductors of germanium (Ge) or silicon (Si), and gallium-arsenic (GaAs) compound semiconductors. The relations between the energy gaps E_g of these semiconduc-

60 tors and the temperature are explained on page 24 of the cited text and are reprinted in Figure 1.

As seen from Figure 1, the energy gaps E_g of Ge, Si and GaAs are 0.80 eV, 1.12 eV and 1.43 eV at the normal temperature normal temperature (300 K) respectively. Their temperature-dependencies are 0.39 meV K⁻¹, 0.24 meV K⁻¹ and 0.43 meV K⁻¹, respectively. By obtaining voltages having values equivalent to or close to the energy gaps E_g, reference voltage generating devices are obtained which have a temperature-

65 dependence one order smaller than those of the forward voltage drop V_F of a PN-junction diode and the

threshold voltage V_{th} of an IGFET as described previously. Furthermore, the voltage obtained is determined by the energy gap E_g inherent to the semiconductor. With, for example, Si, it is determined to be about 1.12 V at the normal temperature substantially independent of the other factors. It is possible to obtain a reference voltage which is not affected by variations in the manufacturing conditions etc.

5 The states of energy levels in the case of doping semiconductors with donor and acceptor impurities are well known. A feature necessary to the present invention is the phenomenon that the energy levels at which the Fermi energies of N-type and P-type semiconductors are located are separated towards a conduction band and towards a valence band with respect to the Fermi energy level E_f of an intrinsic semiconductor. As the densities of the acceptor and donor impurities gets higher, there is a tendency for the energy levels to 5 become more distant from the Fermi level E_f of the intrinsic semiconductor. Hence, the Fermi level E_{fp} of the P-type semiconductor comes close to the top E_v of the valence band, while the Fermi level E_{fn} of the N-type semiconductor comes close to the bottom E_c of the conduction band. Thus, when the difference ($E_{fn} - E_{fp}$) of both the Fermi levels is taken, the energy level difference is approximate to the energy gap E_g possessed by the semiconductor and its temperature-dependence is also approximate to that of the energy gap E_g . This 10 also applies to the differences ($E_{fn} - E_f$) and ($E_f - E_{fp}$) between the Fermi levels of the P-type semiconductor and the intrinsic semiconductor and between the Fermi levels of the N-type semiconductor and the intrinsic semiconductor. In this case, however, the absolute value approaches $E_g/2$. The differences relative to the 15 intrinsic semiconductor will not be described in detail because they are a half of the difference between the P-type and the N-type. As will be described in detail later, the higher the impurity concentration, the lower 20 the temperature-dependency of ($E_{fn} - E_{fp}$). In order to attain a large energy level difference of approximately the energy gap E_g and to attain a low temperature-dependency, it is advantageous to obtain an impurity density as close to the saturation density as possible.

The position of the Fermi levels E_{fn} and E_{fp} involves not only the density of the donor or acceptor impurity but also the donor or acceptor levels E_d or E_a , which differ depending upon impurity material. The nearer the 25 energy level E_d or E_a approaches the conduction band or the valence band respectively, the nearer the Fermi level E_{fd} or E_{fa} comes to one or other. Thus, as the impurity levels E_d and E_a of the donor and acceptor have shallower levels, the difference ($E_{fn} - E_{fp}$) of the Fermi levels approaches the energy gap E_g of the 30 semiconductor.

As the impurity level E_d or E_a of the donor or acceptor is closer to the Fermi level E_f of the intrinsic 35 semiconductor, that is, as it has a deeper level, the difference ($E_{fn} - E_{fp}$) of the Fermi levels becomes increasingly different from the energy gap E_g of the semiconductor. This, however, does not mean that the temperature-dependence degrades, but means that the absolute value of the difference ($E_{fn} - E_{fp}$) of the Fermi levels diminishes. Therefore, the difference ($E_{fn} - E_{fp}$) of the Fermi levels or the difference of work 40 functions is a physical quantity inherent to the semiconductor material, the impurity materials, etc. From another viewpoint, it can become a reference voltage source parallel or similar to, the energy gap E_g of the semiconductor. Thus, the difference ($E_{fn} - E_{fp}$) of the Fermi levels can become a reference voltage source which has a lower temperature-dependence and is less liable to be affected by the manufacturing conditions than the forward voltage drop V_F of a PN-junction or the threshold voltage V_{th} of an IGFET. Therefore, by obtaining the difference ($E_{fn} - E_{fp}$) of the Fermi levels by the use of impurity materials exhibiting donor and 45 acceptor levels E_d and E_a having shallow levels, it is possible to obtain a voltage with a value approximately that of the energy gap E_g of the semiconductor. Also, as regards the setting of a voltage value to be obtained, in the case of intending to attain a comparatively large reference voltage equivalent to the energy gap of the semiconductor, impurities which exhibit shallow levels may be used, and in the case of intending to attain a 50 comparatively small reference voltage, impurities which exhibit deep levels may be used.

50 The relations between the Fermi level E_f and the donor level E_d , acceptor level E_a , donor density N_d , acceptor density N_a and the temperature T will now be described in more detail with reference to Figure 2 and Figure 3. Prior to this description, data on page 30 of the cited text and reprinted in Figure 4 will be referred to in order to explain what levels various impurities have in Ge, Si and GaAs semiconductors and to explain how the impurities are utilized in this invention.

55 Figures 4(a), 4(b) and 4(c) are diagrams which show the energy distributions of various impurities for Ge, Si and GaAs, respectively. In the respective diagrams the numerals indicate energy differences ($E_c - E_d$) from the bottom E_c of a conduction band to levels located above the center of the energy gap, the Fermi level of an intrinsic semiconductor E_f , shown by the broken line, and energy differences ($E_a - E_v$) from the top E_v of a valence band to levels located below the gap center E_f , the unit being eV in both cases.

60 Thus, an impurity material indicated by a small numerical value in each diagram has its level close to the bottom E_c of the conduction band or the top E_v of the valence band, and it is appropriate as an impurity for obtaining a voltage close to the energy gap E_g . For example, for Si which is used most frequently at present, level differences ($E_c - E_d$) and ($E_a - E_v$) respectively exhibited by the donor impurities of Li, Sb, P, As and Bi and the acceptor impurities of B, Al and Ga are the smallest, and both the level differences are below about 65 6% of the energy gap E_g of Si. If differences of temperature from 0 K are ignored, the difference ($E_{fd} - E_{fa}$) of the Fermi levels of N-type Si and P-type Si employing these impurities becomes about 94% to 97% of the energy gap E_g of Si, a value approximately equal to E_g . A donor impurity and an acceptor impurity which exhibit the smallest level differences ($E_c - E_d$) and ($E_a - E_v$) after the above impurities are S (about 16% of E_g) and In (about 14% of E_g), respectively. The difference ($E_{fd} - E_{fa}$) of the Fermi levels of N-type Si and P-type Si employing the respective impurities becomes about 0.85 E_g at 0 K, and the deviation from the energy gap E_g

of Si is as great as about 15%. Thus, the deviation is much greater than those of the impurities mentioned earlier.

Thus, one donor impurity selected from the group consisting of Li, Sb, P, As and Bi and one acceptor impurity selected from the group consisting of B, Al and Ga are suitable as the impurity materials of P-type 5 and N-type Si for obtaining a voltage substantially equal to the energy gap E_g of Si. The other impurities can be used when it is necessary to obtain voltages considerably smaller than the energy gap E_g of Si.

The difference ($E_{F_n} - E_{F_p}$) of Fermi levels will be explained from the physical properties of the materials with reference to Figures 2(a) to 2(d). These Figures are diagrams illustrating the energy levels of semiconductors. Figures 2(a) and 2(b) show the energy level model and the temperature characteristic, respectively, of an 10 N-type semiconductor while Figures 2(c) and 2(d) show the energy level model and the temperature characteristic of a P-type semiconductor.

Carriers in a semiconductor consist of both electrons n_d created by ionization of donor impurities N_d and electron-hole pairs excited from a valence band. When the donor impurity density N_d is sufficiently high, the number of the excited electron-hole pairs is negligible, and the number of conduction electrons, n is given by 15 the equation:

$$n = n_d \quad \dots (1)$$

20 n_d and n are respectively evaluated from the probability at which electrons are trapped by the donor level and the number of electrons which exist in a conduction band, and have values given by the equations: 20

$$25 \quad n_d = N_d \left\{ 1 - \frac{1}{1 + \exp \left(\frac{E_d - E_F}{kT} \right)} \right\} \quad 25$$

$$30 \quad = N_d \cdot \frac{1}{1 + \exp \left(\frac{E_F - E_d}{kT} \right)} \quad \dots (2) \quad 30$$

$$35 \quad \dots (2) \quad 35$$

and

$$40 \quad n = N_c \cdot \exp \left(\frac{E_F - E_c}{kT} \right) \quad \dots (3) \quad 40$$

45 Here, the effective density of states in the conduction band, N_c is given by the equation: 45

$$N_c = 2 \left(\frac{2\pi m^*}{h^2} kT \right)^{3/2}$$

50 where h is Planck's constant, m^* is the effective mass of electron, 50
 k is Boltzmann's constant, and T is the lattice temperature. From Equations (1), (2) and (3),

$$55 \quad N_c \cdot \exp \left(\frac{E_F - E_c}{kT} \right) = \frac{N_d}{1 + \exp \left(\frac{E_F - E_d}{kT} \right)} \quad \dots (4) \quad 55$$

60 and

$$\frac{N_d}{N_c} = \exp \left(\frac{E_F - E_c}{kT} \right) + \exp \left(\frac{2 E_F - E_d - E_c}{kT} \right) \quad \dots (5)$$

Since the Fermi level is supposed to lie near to the bottom of the conduction band E_c , the first term of Equation (5) is negligible, so that the following equation is obtained.

5 $E_F = 1/2 (E_d + E_c) - \frac{1}{2} kT \cdot 1n\left(\frac{N_c}{N_d}\right)$ (6) 5

It can be seen from this equation that, in the case where the impurity concentration density N_d is high, not
10 only at a low temperature, but also at the normal temperature, N_c/N_d approximates to one and 10

$$1n\left(\frac{N_c}{N_d}\right)$$

15 tends to zero so that the Fermi level E_F lies at the intermediate point between the bottom E_c of the conduction band and the donor level E_d and the temperature-dependence becomes substantially equal to the temperature characteristic of E_c . 15

However, in the case where the temperature has become sufficiently high, the electron-hole pairs excited
20 from the valence band are predominant, the influences of the impurities lessen and the Fermi level E_{Fn} in the N-type semiconductor approaches the level E_i of the intrinsic semiconductor. This relationship is illustrated
25 in Figure 2(b). 20

This also applies to the case of a P-type semiconductor containing only an acceptor impurity, as shown in Figure 2(c). When the temperature is low and the acceptor impurity density is high, the Fermi level E_{fp} in the
25 P-type semiconductor lies at a substantially intermediate position between the top E_v of the valence band and the acceptor level E_a . When the temperature rises, it approaches the Fermi level E_i of the intrinsic semiconductor. 25

The temperature-dependence of the Fermi level E_{fp} in the P-type semiconductor is illustrated in Figure
2(d).

30 The relations between the temperature-dependence of the Fermi levels E_{fp} and E_{fn} and the impurity densities have been explained on physical properties. Now, by taking as an example the Si semiconductor which is used most frequently in practice at this present time, the difference of the Fermi levels ($E_{fn} - E_{fp}$) and its temperature-dependence in practical use will now be discussed with reference to data on page 37 of the cited text. The data are reprinted in Figure 3. 30

35 In conventional processes for manufacturing a Si semiconductor integrated circuit, only boron B and phosphorus P are used as impurity materials. Their high impurity densities are 10^{20} atoms cm^{-3} . However, even when the donor and acceptor impurity densities N_d and N_a are made 10^{18} atoms cm^{-3} which is lower by two orders, the difference ($E_{fn} - E_{fp}$) of the Fermi levels of the N-type semiconductor and the P-type semiconductor is $0.5 - (-0.5) = 1.0$ eV at 300 K as can be seen from Figure 3, and it is a value comparatively close to the energy gap $E_g \approx 1.1$ eV at the same temperature. The changes of this difference with temperatures are from about 1.04 eV to 0.86 eV in a range of from 200 K to 400 K (-70°C to 130°C), and the rate of change is 0.9 mV K^{-1} . This is a small value of approximately a third in comparison with 2 to 3 mV K^{-1} , the rates of change with temperatures of the threshold voltage V_{th} of an IGFET and the forward drop voltage V_F of a diode as stated previously. 40

45 When the impurity densities are 10^{20} cm^{-3} or higher, the Fermi level difference becomes substantially equal to the silicon energy gap (E_g)_{Si} = 1.1 eV, and the changing rate versus temperatures becomes about 0.2 mV K^{-1} which is a sufficiently small value. 45

Thus, if the impurity concentrations are about 10^{18} cm^{-3} or higher, a temperature-dependence which is reduced to at least a half to a third of those of the prior art can be attained. Preferably, the impurity concentrations are 10^{20} cm^{-3} or higher, and most preferably, they are the saturation densities or degenerate densities. 50

55 One method of obtaining the voltage corresponding to the difference of the Fermi levels ($E_{fn} - E_{fp}$), ($E_{fn} - E_i$) is to utilize the difference of the threshold voltages V_{th} of two MOSFETs with channels of the same conductivity type which have semiconductor gate electrodes that are formed on gate insulating films formed under substantially the same conditions on different surface areas of an identical semiconductor body and that are made of materials being of an identical semiconductor substance (for example, silicon) but having different conductivity types. 55

60 Each of Figures 59 and 60 depicts conceptually the sectional structures of the respective FETs formed within a complementary MOS integrated circuit (CMOSIC). For the sake of brevity, the MOS transistor whose gate electrode is made of a P^+ -type semiconductor shall be called the " P^+ gate MOS", the MOS transistor whose gate electrode is made of an N^+ -type semiconductor shall be called the " N^+ gate MOS", and the MOS transistor whose gate electrode is made of an intrinsic or i-type semiconductor shall be called the " i gate MOS". In Figure 60, the left half shows P^+ , i , and N^+ gate P-channel MOS transistors, while the right half shows P^+ , i and N^+ gate N-channel MOS transistors. 60

The differences of threshold voltages among the MOSFETs, (Q₁) - (Q₃) and (Q₄ - (Q₆) in Figure 60, take values as shown in the following table:

TABLE							(Unit: volt)	
5		Q ₁	Q ₂	Q ₃	Q ₄	Q ₅	Q ₆	5
	10	Q ₁	0.55	1.1	—	—	—	
10	10	Q ₂	0.55	0.55	—	—	—	10
	15	Q ₃	1.1	0.55	—	—	—	
15	15	Q ₄	—	—	—	0.55	1.1	15
	20	Q ₅	—	—	—	0.55	0.55	
20	20	Q ₆	—	—	—	1.1	0.55	20

As will be described in detail later, Figures 73(a) to 73(f) illustrate sectional views of the principal steps which indicate that the P⁺ gate MOS and the N⁺ gate MOS can be fabricated without altering or adding any step of a conventional process for manufacturing a complementary MOS integrated circuit (CMOS IC).

Figures 65(a) and 65(b) or Figures 66(a) and 66(b) depict a plan view and a sectional structural view respectively of N⁺ gate or P⁺ gate P-channel MOS transistors to be actually used in circuit structures.

Referring to Figures 65(a) and 65(b) or Figures 66(a) and 66(b), in order to form a self-alignment structure, a P-type impurity is diffused in both those end parts E_S and E_D of the gate electrode G formed of an i-type or intrinsic semiconductor which are close to a source S and a drain D, for both the P⁺ gate MOS and the N⁺ gate MOS because the MOS transistor has the P-channel in this example. In a central part C_P of the gate electrode G, a P-type impurity is diffused for the P⁺ gate MOS, and an N-type impurity is diffused for the N⁺ gate MOS. A region / in which no impurity is diffused is provided between the central region and both the end parts E_S and E_D close to the source and the drain. Thus, the difference between the P⁺ gate MOS and the N⁺ gate MOS is only whether the region of the central region part C_P of the gate is of P-type semiconductor or N-type semiconductor.

Shown in Figures 65(a) and 65(b) or Figures 66(a) and 66(b), is an N⁻ silicon substrate 101, a P⁺ source region 108, a P⁺ drain region 113, a gate oxide film 105, a thick field oxide film 108, and another oxide film 111. As is clear from Figures 65(a) or Figure 66(a), a plurality of P⁺ source regions 108 are electrically connected to one another by an interconnection layer 114, a plurality of P⁺ drain regions 113 are electrically connected to each other by an interconnection layer 112, and a plurality of gate electrodes G are electrically connected to one another by an interconnection layer 115.

In order to reduce the variation of the effective channel lengths of the MOS transistors, due to the fact that the P-type impurity diffused regions at both the end parts E_S and E_D of the gate electrodes G, formed for the self-alignment, shift to either the left or right side (source side or drain side) during manufacture because of an error in mask alignment, the columns of the source regions and the drain regions are alternately arranged, and the columns are arranged so that the left half and the right half may be put into a linear symmetry with respect to the channel direction as a whole. Thus, even when the shifting of the mask alignment with respect to the channel direction (leftward or rightward shifting) changes the effective channel lengths of the FETs in the respective columns, the average effective channel lengths of the P⁺ gate MOS and the N⁺ gate MOS in the respective columns connected in parallel have the changes cancelled out overall and become substantially constant.

Figures 73(a) to 73(f) illustrate how the P⁺ gate MOS and the N⁺ gate MOS are constructed by the use of the conventional manufacturing process for a silicon gate CMOS IC.

In Figure 73(a) is shown an N-type silicon semiconductor 101 having a resistivity of 1 Ωcm to 8 Ωcm, on which a thermal oxidation film 102 is grown to a thickness of about 4,000 Å to 16,000 Å. In an area of the film, a window for selective diffusion is provided by the photoetching technique. Boron, to serve as a P-type impurity, is non-implanted in a quantity of approximately 10¹¹ to 10¹³ cm⁻² at energy of 50 keV to 200 keV, and is thermally diffused for about 8 to 20 hours, to form a P⁻ well region 103 which serves as a substrate of an N-channel MOS transistor.

In Figure 73(b), the thermal oxidation film 102 is entirely removed, a new thermal oxidation film 104 is formed about 1 μm to 2 μm, and a region of this film corresponding to the source, drain and gate of the MOS transistor is removed by etching. Then, a gate oxide film 105 which is about 300 Å to 1,500 Å thick is formed. On the resultant substrate, polycrystalline Si 106 being of i-type, or intrinsic semiconductor, is grown to a thickness of about 2,000 Å to 6,000 Å. By etching, it is removed with the gate part G of the MOS transistor left behind.

65 In Figure 73(c), a mask oxide film 107 is formed by vapour growth, and its regions under which a P-type

impurity is to be diffused are removed by the photoetching technique. Subsequently, boron, being the P-type impurity, is diffused at a high density of about 10^{20} to 10^{21} cm^{-3} to form a source region 108 and a drain region 113 of the P-channel MOS transistor and simultaneously to form a gate electrode of P-type semiconductor.

5 In Figure 73(d), as in the foregoing, a mask oxide film 109 is formed by vapour growth, and its regions under which an N-type impurity is to be diffused are removed by the photoetching technique. Then, phosphorus, being the N-type impurity, is diffused at a high density of about 10^{20} to 10^{21} cm^{-3} , to form a source region 110 and a drain region 116 of the N-channel MOS transistor and simultaneously to form a gate electrode of an N-type semiconductor.

10 In Figure 73(e), the oxide film 109 is removed. An oxide film 111 which is approximately 4,000 Å to 8,000 Å thick is formed by vapour growth, and its region corresponding to an electrode leading-out portion is removed by the photoetching technique. Thereafter, a metal (Aluminium) is evaporated, and an electrode interconnection portion 112 is formed by the photoetching technique.

In Figure 73(f), the resultant substrate is covered with an oxide film being 1 μm to 2 μm thick by vapour 15 growth.

The threshold voltage of the MOS transistor employing the semiconductor for the gate electrode will be described with reference to Figures 5(a) to 5(d). First, in the case of the P⁺ gate MOS, the energy band diagram of Figure 5(a) shows that the following equation holds;

20

$$-\mathbf{qV}_G + \underbrace{\mathbf{q}\phi_{FP} + E_g/2 + q\chi}_{\phi_{MP^+}} = \mathbf{qV}_0 + \mathbf{q}\phi_{srf}$$

25

$$+ \underbrace{q\chi + E_g/2 - Q\phi_B}_{\phi_{Si}} \dots\dots (7)$$

30

where V_G is the potential difference between a semiconductor substrate and a gate electrode (P⁺ semiconductor),

χ is the electron affinity,

E_g is the energy gap,

35 35 ϕ_{srf} is the surface potential of an N-type semiconductor substrate, ϕ_{FP} is the Fermi potential of a P-type semiconductor with reference to the Fermi potential of an intrinsic semiconductor,

ϕ_B is the Fermi potential of the N-type semiconductor substrate with reference to the Fermi potential of the intrinsic semiconductor,

40 40 q is the unit charge of electron,

V_0 is the potential difference applied to an insulator,

E_c is the bottom of a conduction band,

E_v is the top of a valence band,

E_f is the Fermi level of the intrinsic semiconductor.

45 45 In Equation (7), the work function of the gate electrode is denoted as ϕ_{MP^+} and the work function of the semiconductor is similarly denoted as ϕ_{Si} . Then,

$$\phi_{MP^+} = \chi + E_g/2q + \phi_{FP} \dots\dots (8)$$

50 50

$$\phi_{Si} = \chi + E_g/2Q - \phi_F \dots\dots (9)$$

Therefore,

55

$$V_0 = -V_G + \phi_{MP^+} - \phi_{Si} - \phi_{srf} \dots\dots (10)$$

60 60 From the relation of charges in Figure 5(b),

$$-C_{ox} \cdot V_0 + Q_{ss} + Q_1 + Q_B = 0 \dots\dots (11)$$

where C_{ox} is the capacitance of the insulator per unit area,
 Q_{ss} are the fixed charges in the insulator,
 Q_b are the fixed charges due to ionization of impurities in the semiconductor substrate,
 Q_i are carriers formed as a channel.

5 From (10) and (11),

5

$$\begin{aligned} & -C_{ox}(-V_G + \phi_{MP}^+ - \phi_{Si} - \phi_{Srf}) \\ 10 & + Q_{ss} + Q_i + Q_D = 0 \end{aligned} \quad \dots \quad (12) \quad 10$$

The gate voltage V_G at the time when the channel Q_i is formed is the threshold voltage. Therefore, letting V_{thp}^+ denote the threshold voltage of the P^+ gate MOS,

$$15 \quad V_{thp}^+ = V_G|_{a=0} = \phi_{MP}^+ - \phi_{Si} - \phi_{Srf} - Q_{ss}/C_{ox} - Q_D/C_{ox} \quad \dots \quad (13) \quad 15$$

20 At this time, $\phi_{Srf} = 2\phi_F$.

20

Similarly, in the N^+ gate MOS transistor, only the work function ϕ_{MN}^+ of the gate electrode differs, as shown in the following equation:

$$25 \quad \phi_{MN}^+ = \chi + E_g/2q + \phi_{FN}^+ \quad \dots \quad (14) \quad 25$$

Hence, the threshold voltage V_{thN}^+ of the N^+ gate MOS is given by the equation:

$$30 \quad V_{thN}^+ = \phi_{MN}^+ - \phi_{Si} - \phi_{Srf} - Q_{ss}/C_{ox} - Q_D/C_{ox} \quad \dots \quad (15) \quad 30$$

where $\phi_{Srf} = 2\phi_F$.

35 Thus, the difference $V_{thp}^+ - V_{thN}^+$ of the threshold voltages of the P^+ gate MOS and the N^+ gate MOS is given by the equation

35

$$40 \quad V_{thp}^+ - V_{thN}^+ = \phi_{MP}^+ - \phi_{MN}^+ = \phi_{FP}^+ - \phi_{FN}^+ \quad \dots \quad (16) \quad 40$$

which is equal to the difference of the Fermi potentials of the semiconductors making up the gate electrodes. This can be seen from comparison of Figures 5(a) and 5(c) since the gate voltage at the time when the same charge profile is established is equal to the difference of the work functions of the gate electrodes and the 45 difference of the Fermi levels.

45

While the above description has been made by taking the P^- -channel MOS transistor as an example, the same applies to the case of the N^+ -channel MOS transistor.

From the above description, it is clear that a voltage substantially equal to the energy gap E_g can be derived from the difference of the threshold voltages of the P^+ gate MOS and the N^+ gate MOS.

50 Alternatively, the voltage of the energy gap E_g can be derived from the difference of the threshold voltage of a MOS whose gate electrode is made of an intrinsic semiconductor (hereinafter referred to as the "*i* gate MOS") and the threshold voltage of the P^+ gate MOS or the N^+ gate MOS.

50

Letting V_{thi} denote the threshold voltage of the *i* gate MOS, since the Fermi level of the intrinsic semiconductor is 0 (zero) (as the Fermi level of the intrinsic semiconductor is made the reference), the 55 difference of the threshold voltages of the *i* gate MOS and the P^+ gate MOS is given by the equation:

55

$$|V_{thi} - V_{thp}^+| = |0 - \phi_{FP}^+| \approx 1/2 E_g \quad \dots \quad (17)$$

60 The difference of the threshold voltages of the *i* gate MOS and the N^+ gate MOS is given by the equation:

60

$$|V_{thi} - V_{thN}^+| = |\phi_{FN}^+ - 0| \approx 1/2 E_g \quad \dots \quad (18)$$

It is clear that the differences provide a voltage of half of the energy gap E_g .

The voltage which is obtained owing to the difference of the threshold voltages of the *i* gate MOS and the P^+ gate or N^+ gate MOS is very useful in that it is approximately 0.55 V and suitable for a low reference voltage source, and hence, a reference voltage source of high precision is easily obtained, not only by the

5 manufacturing process of the CMOS integrated circuit, but also by the manufacturing process of
single-channel MOS integrated circuit because the doping of gate electrodes with an impurity can be carried
out in one step.

Figures 67(a) and 67(b) to Figures 72(a) and 72(b) depict plan patterns and sectional structures along lines
A - A in the plan patterns, of P^+ gate, *i* gate and N^+ gate P-channel and N-channel MOS transistors

10 respectively, to be used in circuit structures.

In the figures, similarly to the examples of Figures 65(a) and 65(b) or Figures 66(a) and 66(b), P- or N-type regions of a source and a drain are formed by the diffusion of an impurity by employing polycrystalline Si for a mask. In order to allow a margin for the mask alignment between the mask for selectively diffusing a P-type impurity or an N-type impurity and the source and drain regions, the same impurity as that of the source and 15 drain regions is diffused in both end parts E_S and E_D of a gate electrode G adjoining the source S and drain D in both the P^+ gate MOS and the N^+ gate MOS, In, for example, the P-channel MOS, boron, which is the P-type impurity, is diffused. In a central part of the gate electrode, a P-type impurity is diffused for the P^+ gate MOS, and an N-type impurity is diffused for the N^+ gate MOS.

Figures 67(a) and 67(b), Figures 68(a) and 68(b) and Figures 69(a) and 69(b) represent plan views and 20 sectional views of P-channel MOS transistors of the P^+ gate, *i* gate and N^+ gate, respectively, while Figures 70(a) and 70(b), Figures 71(a) and 71(b) and Figures 72(a) and 72(b) represent N-channel MOS transistors of the N^+ gate, *i* gate and P^+ gate, respectively.

In Figures 67(a) and 67(b) to Figures 72(a) and 72(b), in order to reduce the variation of the effective channel lengths of the MOS transistors due to the fact that those regions at both the end parts E_S and E_D of 25 the gate electrodes G which are formed for the self-alignment and in which the same impurity as that of the source and drain regions is diffused, shift to either the left or right side (source side or drain side) during manufacture because of an error in the mask alignment, the columns of the source regions and the drain regions are alternately arranged, and the columns are arranged so that the left half and the right half may be put into a line symmetry with respect to the channel direction as a whole. Thus, even when the shifting of the 30 mask alignment with respect to the channel direction (leftward or rightward shifting) changes the effective channel lengths of the FETs in the respective columns, the average effective channel lengths of the P^+ gate MOS, *i* gate MOS and the N^+ gate MOS in the respective columns connected in parallel have the changes cancelled out overall and become substantially constant.

Figures 74(a) to 74(d) illustrate how the P^+ gate MOS and the N^+ gate MOS are constructed by the use of 35 conventional silicon gate CMOS manufacturing process.

In Figure 74(a) is shown an N-type silicon semiconductor having a resistivity of $1\Omega\text{cm}$ to $8\Omega\text{cm}$, on which a thermal oxidation film 102 is grown to a thickness of about $4,000 \text{ \AA}$ - $16,000 \text{ \AA}$. In an area of the film, a window for selective diffusion is provided by the photoetching technique. Boron to serve as a P-type impurity is ion-implanted in a quantity of approximately 10^{11} - 10^{13} cm^{-2} at energy of 50 keV to 200 keV, 40 whereupon it is thermally diffused for about 8 to 20 hours, thereby to form a P^- well region 103 which serves as a substrate of an N-channel MOS transistor.

In Figure 74(b), the thermal oxidation film 102 is entirely removed, a new thermal oxidation film 104 is formed about $1 \mu\text{m}$ to $2 \mu\text{m}$, and a region of this film corresponding to the source, drain and gate of the MOS transistor is removed by etching. Thereafter, a gate oxide film 105 which is about 300 \AA - $1,500 \text{ \AA}$ thick is 45 formed. On the resultant substrate, polycrystalline Si 106 being of the *i*-type or intrinsic semiconductor is grown to a thickness of $2,000 \text{ \AA}$ - $6,000 \text{ \AA}$. By etching, it is removed with the gate part G of the MOS transistor left behind..

In Figure 74(c), a mask oxide film 107 is formed by vapour growth, and its regions under which a P-type impurity is to be diffused are removed by the photoetching technique. Subsequently, boron to become the 50 P-type impurity, is diffused at a high density of about 10^{20} to 10^{21} cm^{-3} , to form a source region 108 and a drain region 113 of the P-channel MOS transistor and simultaneously to form a gate electrode of a P-type semiconductor.

In Figure 74(d), as in the foregoing, a mask oxide film 109 is formed by vapour growth, and its regions under which an N-type impurity is to be diffused are removed by the photoetching technique. Then, 55 phosphorus to become the N-type impurity at a high concentration of about 10^{20} - 10^{21} cm^{-3} is diffused, to form a source region 110 and a drain region 116 of the N-channel MOS transistor and simultaneously to form a gate electrode of an N-type semiconductor.

Subsequently, the oxide film 109 is removed. An oxide film which is approximately $4,000 \text{ \AA}$ - $8,000 \text{ \AA}$ thick is formed by vapour growth, and its region corresponding to an electrode leading-out portion is removed by 60 the photoetching technique. Thereafter, a metal (Aluminium) is evaporated, and an electrode interconnection portion is formed by the photoetching technique.

Subsequently, the resultant substrate is covered with an oxide film being $1 \mu\text{m}$ to $2 \mu\text{m}$ thick by vapour growth.

Here, in Figure 74(d), Q_3 and Q_4 indicates MOS transistors which constitute a conventional CMOS inverter, 65 and Q_1 and Q_2 indicate P^+ gate and N^+ gate MOS transistors for generating a reference voltage.

Figures 75(a) to 75(d) show sections in the manufacturing process of P⁺ gate MOS and i gate MOS transistors of the P-channel type. In this example, the steps up to Figure 75(c) are the same as those up to Figure 74(c). In Figure 75(d), however, the N-type impurity is diffused without removing an oxide film 109b overlying the gate of the MOSFET Q₂.

5 Figures 76(a) to 76(d) show sections in the manufacturing process of P⁺ gate MOS and N⁺ gate MOS transistors of the N-channel type. 5

Figures 77(a) to 77(d) show sections in the manufacturing process of N⁺ gate MOS and i gate MOS transistors of the N-channel type.

A process in an N-channel MOS semiconductor integrated circuit will now be described with reference to 10 sections illustrated in Figures 78(a) to 78(e). The process has steps as described below. 10

(1) A P-type semiconductor substrate 101 having a resistivity of 8 - 20 Ωcm is prepared, and a thermal oxidation film 102 which is 1 μm thick is formed on the surface of the substrate.

(2) In order to expose the semiconductor substrate surface corresponding to portions in which MISFETs are to be formed, selected parts of the thermal oxidation film are etched.

15 (3) A gate oxide film (SiO₂) 103, which is 750 to 1,000 Å thick, is formed on the exposed semiconductor substrate surface (Figure 78(a)). 15

(4) That part of the gate oxide film 103 which is to come into direct contact with a polycrystalline silicon layer is selectively etched, to form a direct contact hole 103a. (Figure 78(b)).

20 (5) Silicon is deposited by the CVD (Chemical Vapor Deposition) process onto the whole major surface of the semiconductor substrate 101 having the oxide film 102, the gate oxide film 103 and the contact hole 103a, 20 to form the polycrystalline silicon layer which is 3,000 to 5,000 Å thick.

(6) Selected parts of the polycrystalline silicon layer 104 being of the i-type or intrinsic semiconductor are etched. (Figure 78(c)).

(7) A CVD-mask SiO₂ film is deposited to a thickness of 2,000 to 3,000 Å on the whole major surface of the 25 semiconductor substrate 101 by the CVD process. 25

(8) The CVD-mask SiO₂ film 105 is selectively left only at high resistance parts such as memory cell load resistors, and on the polycrystalline silicon layer of intrinsic level gate portions 104a. (Figure 78(d)).

(9) Phosphorus is diffused into the semiconductor substrate 101, to form source regions and drain regions 106 at an impurity density of 10²⁰ atoms cm⁻³. Simultaneously, the impurity is also introduced into 30 the polycrystalline silicon layer, to form gate electrodes 104b, a direct contact 104c and a polycrystalline silicon interconnection portion 104d. (Figure 78(d)). 30

(10) A PSG (Phospho-Silicate-Glass) film 107 is formed at a thickness of 7,000 to 9,000 Å on the entire major surface of the semiconductor substrate 101.

(11) Al (aluminium) is thereafter evaporated on the whole area of the major surface of the semiconductor 35 substrate 101, to form an Al film 108 which is 1 mm thick. 35

(12) The Al film is selectively etched to form interconnection regions 108. (Figure 78(e)).

The principle of obtaining the difference of Fermi levels described above and actual examples will be briefly explained again. Figure 58 shows enhancement type p-channel Metal Insulator Semiconductor Field-Effect transistors (herein referred to as MISFETs) Q₁ and Q₂ which are formed on an n-type 40 semiconductor substrate 1. The gate electrodes of the respective MISFETs are made of conductor layers which are constructed in such a way that polycrystalline silicon layers are doped with semiconductor impurities of different conductivity types. More specifically, the MISFETs Q₁, Q₂ are fabricated as follows. As shown in Figure 58, p⁺-type semiconductor region 4, 5 to form the sources and drains of MISFETs are selectively formed on an n-type semiconductor substrate 1. Gate insulating films 2 are formed on the areas 45 of the surface of the semiconductor substrate between the opposing source and drain regions 4, 5, and polycrystalline silicon layers 6 and 6' are formed on the gate insulating films 2. The polycrystalline silicon layer to constitute the gate 6' of one MISFET Q₁ is doped with a semiconductor impurity of the same conductivity type as that of the substrate (n-type). The polycrystalline silicon layer to constitute the gate 6 of the other MISFET Q₂ is doped with a semiconductor impurity of the conductivity type opposite to that of the 50 substrate (p-type).

The threshold voltages (V_{thQ_1} , V_{thQ_2}) of the respective MISFETs Q₁, Q₂ in the above construction are derived from the following equations:

55 $V_{thQ_1} = \phi_{Mn} + Q_{ss}/C_{ox} + Q_D/C_{ox}$ (19) 55

$V_{thQ_2} = \phi_{Mp} + Q_{ss}/C_{ox} + Q_D/C_{ox}$ (20)

60 Here, ϕ_{Mn} and ϕ_{Mp} denote the work functions between the gates of the respective MISFETs Q₁, Q₂ and the substrate, C_{ox} the gate capacitance per unit area Q_{ss} the surface charge, and Q_D the charge of a substrate depletion layer.

When the difference of the threshold voltages of both the MISFETs Q₁, Q₂ is evaluated, it becomes the 65 difference ($\phi_{Mp} - \phi_{Mn}$) between the work functions which are the first terms of the right-hand sides of

Equations (19) and (20), and it can be derived as a voltage which corresponds to the energy gap of silicon. Since this voltage becomes a voltage determined by the energy gap of silicon, deviations in the manufacture are not involved. In addition, the temperature-dependence is extremely small. The reason why the threshold voltages of MISFETs exhibit large deviations is that the second terms (Q_{ss}/Q_{ox}) and the third terms (Q_0/C_{ox}) 5 on the right-hand sides of Equations (19) and (20) fluctuate depending upon the conditions of manufacture. In this embodiment, the MISFETs Q_1 , Q_2 are manufactured under the same conditions and hence the second terms and third terms on the right-hand sides of equations (19) and (20) are made substantially equal. By evaluating the difference between the right-hand sides, the second and third terms are cancelled. Thus, the magnitude equivalent to the energy gap is used as an output voltage.

10 Since the MISFET Q_2 has the source, drain and gate electrode formed by the use of the semiconductor impurity of an identical conductivity type, the conventional manufacturing technology of a silicon gate MISFET, in which the semiconductor impurity diffusions of its source and drain and its gate electrode are performed simultaneously, can be employed. However, the gate electrode of the MISFET Q_1 cannot be formed simultaneously with the source and drain and therefore needs to be formed by a separate step. To 15 perform this, a method is considered wherein the MISFETs Q_1 , Q_2 as above described are formed while employing the conventional manufacturing technology of the silicon gate MISFET in which a gate insulating film and a field insulating film are used as a mask. Alternatively, a measure illustrated in Figure 61 is considered. Those parts 6a, 6'a of gate electrodes 6, 6' of MISFETs Q_1 , Q_2 which are close to sources and drains are made gate electrode portions in which a p-type semiconductor of the same conductivity type as 20 that of the sources and drains is diffused. The central parts of the gate electrodes which are not doped with any semiconductor impurity, that is, which are made of the intrinsic semiconductor (i-type), are selectively formed with a gate electrode portion 6b in which a p-type impurity is diffused and a gate electrode portion 6'b in which an n-type semiconductor impurity is diffused, respectively. Herein, the parts doped with no semiconductor impurity have been disposed in consideration of the misregistration of the mask alignment in 25 the case of forming the gate electrode portions 6b, 6'b of the different semiconductor impurities in the selected regions. In this method, the gate electrode portions 6a, 6b of the MISFET (Q_2) are formed by the same step as that for the diffusion of the source and drain.

Each of the MISFETs in the above construction has the gate electrode which is made up of the plurality of gate electrode portions. The plurality of gate electrode portions are connected together and the difference of 30 threshold voltages of both the MISFETs Q_1 , Q_2 are obtained. Hence, threshold voltage components based on the electrode portions of the same structures (gate electrode portions 6a and 6'a, and i-type electrode portions) in both the MISFETs Q_1 , Q_2 are cancelled. In addition, regarding the MISFETs owing to the gate electrode portions 6b, 6'b, the second and third terms on the right-hand sides of Equations (19) and (20) are not cancelled. As the difference voltage, there is obtained the voltage which corresponds to the silicon 35 energy gap being the difference of the work function between the central parts 6b, 6'b of the gate electrodes and the substrate as described previously, and which is approximately 1.1 V.

Figure 62 shows a complementary insulated gate field-effect transistor integrated circuit (CMOSIC) according to another embodiment of this invention. P-channel MOS transistors A, B and C are formed on an N-type silicon body 1, while N-channel MOS transistors D, E and F are formed on a well layer 2 in which a 40 P-type impurity is diffused at a low concentration. A reference voltage generating device is constructed by utilizing the difference between the threshold voltages of the MOS transistors A and B, the MOS transistors A and C or the MOS transistors B and C, or the difference between the threshold voltages of the MOS transistors D and E, the MOS transistors D and F or the MOS transistors E and F. Shown in Figure 62 is a thick field oxide film (SiO_2) 3, and a gate oxide film (SiO_2) 4. Also shown is a P-type semiconductor region 5 for the 45 source or drain of the P-channel MOSFET, and an N-type semiconductor region 6 for the source or drain of the N-channel MOSFET, P-type polycrystalline silicon 7, N-type polycrystalline silicon 8, and the intrinsic semiconductor or i-type polycrystalline silicon 9. The reference voltage generating device derives the Fermi level difference among the materials 7, 8 and 9 in the form of the voltage.

Figure 63 shows an embodiment which is a further improvement on the embodiment of Figure 62. P-type 50 impurity layers 10 shown in Figure 63 are disposed under the gate oxide films 4 in a manner to overlap with the central parts 8 and 9 of the gate electrodes of the respective transistors B and C in Figure 62, and the transistor A is also provided with a P-type impurity layer 10 so as to have an effective channel length equal to those of the transistors B and C. Also, N-type impurity layers 11 shown in Figure 63 are provided under the gate oxide films 4 in a manner to overlap with the central parts 7 and 9 of the gate electrodes of the 55 respective transistors E and F in Figure 62, and the transistor D is also provided with an N-type impurity layer 11 so as to have an effective channel length equal to those of the transistors E and F. The effective channel lengths of the transistors A, B and C or the transistors D, E and F can be made substantially equal by providing the P-type impurity layers 10 or the N-type impurity layers 11. Hence, the characteristics between the drain currents and gate voltages of the transistors A, B and C or the transistors D, E and F become curves 60 which are parallel to one another and which shift in the direction of the gate voltage axis by the differences of the Fermi levels of the polycrystalline silicon materials at the central parts of the gate electrodes of these transistors. Therefore, the differences of the threshold voltages of the transistors can be obtained with high precision in reference voltage generating circuits to be described later.

The temperature-dependence of the differences of the threshold voltage of the three sorts of IGFETs are 65 very small because the temperature-dependence of the differences of the Fermi levels of the gate electrode

semiconductors are low.

Figures 79(a) to 79(e) illustrate a method of manufacturing the CMOSIC shown in Figure 63. The process has steps as described below.

(a) A low concentration P-type well region 102 is formed in an N-type silicon body 101 by the conventional selective diffusion process. Subsequently, a field oxide film 103 is formed. After forming a gate oxide film 104 in recesses of the film 103, a P-type impurity layers 105 and an N-type impurity layers 106 are formed by conventional selective ion implantation processes. 5

(b) Polycrystalline silicon gate electrodes 107 are formed by conventional chemical vapour deposition and photoetching. At this stage, the electrodes 107 are made of the intrinsic semiconductor.

10 (c) A mask oxide film 108 is formed on selected areas by chemical vapour deposition. Using it as a mask, source and drain layers 109 of P-channel MOSFETs and P-type polycrystalline layers 110 are formed by the 10 selective diffusion of a P-type impurity.

(d) A mask oxide film 108' is formed on selected areas by chemical vapour deposition. Using it as a mask, source and drain layers 111 of N-channel MOSFETs and N-type polycrystalline layers 112 are formed by the 15 selective diffusion of an N-type impurity.

(e) A phosphosilicate glass film 113 is deposited, in which contact holes and aluminium electrodes 114 are formed. The device is then complete. 15

Figure 64 shows another embodiment of the structure of IGFETs which form the reference voltage generating device according to the present invention and which have gate electrodes of different Fermi levels. Here, IGFETs A, B and C have a gate electrode which is made of P-type silicon 7, a gate electrode whose ends are made of P-type silicon 7 and whose central part is made of intrinsic silicon 4 and a gate electrode whose ends are made of P-type silicon 7 and whose central part is made of aluminium 12, respectively. These gate electrodes lie on the gate oxide films (SiO_2) 3 which are formed on different surface areas of an identical N-type silicon body 1 under substantially the same conditions. Further, the IGFETs have 20 source and drain layers 8. When the threshold voltage V_{TH} of the IGFET A is made -0.8 V, that of the IGFET B 20 becomes approximately -1.40 V, and that of the IGFET C becomes approximately -1.95 V. They produce differences which are substantially equal to the differences of the Fermi levels of the Si and Al materials at the central parts of the gate electrodes. 25

This embodiment makes use of the fact that the temperature-dependence of the difference of 30 approximately 1.15 eV between the Fermi levels of the high concentration P-type silicon and the aluminium or the difference of approximately 0.60 eV between the Fermi levels of the intrinsic silicon and the aluminium is low. 30

Figures 80(a) to 80(d) illustrate an embodiment of a method of manufacturing a P-channel IGFET integrated circuit which includes all the IGFETs A, B and C shown in Figure 64.

35 The method has stages as described below. 35

(a) A thick field oxide film (SiO_2) 2 having recesses is formed on the surface of an N-type silicon body 1, a gate oxide film 3 is formed in the recesses, and a polycrystalline silicon layer 4 is deposited by chemical vapour deposition. The polycrystalline silicon layer 4 is of the intrinsic semiconductor. Further, a mask oxide film 6 is formed on a part of the layer 4 by chemical vapour deposition.

40 (b) The polycrystalline silicon layer is selectively removed by the conventional photoetching process, 40 and a P-type impurity such as boron is thermally diffused, to form source and drain layers 8 and P-type polycrystalline silicon layers 7. At this time, the part of the polycrystalline silicon layer 4 covered with the oxide film 6 remains an intrinsic semiconductor.

(c) An insulating film 9 such as phosphosilicate glass film is deposited by chemical vapour deposition, 45 and in which contact holes are formed. At this time, a contact hole 10 is also formed in the central part of a gate electrode in an area to become an IGFET C. 45

(d) Aluminium electrodes 11 and 12 are formed, and a heat treatment is conducted at 380 to 540°C for 30 minutes to 3 hours. Then, the polycrystalline silicon at the contact hole 10 diffuses towards the upper surface of the aluminium layer owing to its alloying reaction with the aluminium, and a structure in which the 50 aluminium and the gate oxide film lie in direct contact is established. The method of manufacturing the P-channel IGFET integrated circuit as illustrated in Figures 80(a) to 80(d) is also applicable to the manufacture of a complementary MIS integrated circuit substantially unchanged. 50

The alloying reaction may be replaced with an alternative in which the central part of the gate electrode is removed by photoetching, whereupon aluminium is brought into direct contact with the gate insulating film. 55

The reference voltage generating device based on such a construction exhibits a small temperature-dependence and small manufacturing deviations, so that it can be utilized for various electronic circuits. 55

Figure 81(d) shows the structure of IGFETs A, B, C and D which have threshold voltage differences based on the Fermi level differences of gate electrodes in accordance with another embodiment of the present invention. The IGFET A is a P-channel MOSFET having a gate electrode made of P-type silicon 11, while the 60 IGFET B is a P-channel MOSFET having a gate electrode whose both end parts are made of P-type silicon 11 and whose central part is made of N-type silicon 8. The IGFET C is an N-channel MOSFET having a gate electrode made of N-type silicon 8, while the IGFET D is an N-channel MOSFET having a gate electrode whose both end parts are made of N-type silicon 8 and whose central part is made of P-type silicon 11. A reference voltage generating device is constructed by employing a voltage based on the difference between 65 the threshold voltages of the MOSFETs A and B or the MOSFETs C and D. 65

Figures 81(a) to 81(d) illustrate a method of fabricating a MOS integrated circuit which includes the IGFETs A, B, C and D.

The method has stages as described below.

(a) A P-type well region 2 is formed in an N-type silicon body 1, and a thick field oxide film 3 having recesses is formed. Then, a gate oxide film 4 is formed in the recesses of the oxide film 3, and a film 5 of polycrystalline silicon, being the intrinsic semiconductor, is deposited and worked by the photoetching process. 5

(b) A mask oxide film 6 is formed on selected areas by chemical vapour deposition. Using it as a mask, an N-type impurity such as phosphorus is diffused into selected regions, whereby N-type regions 7 to become 10 the sources and drains of N-channel MOSFETs and N-type polycrystalline layers 8 are formed. 10

(c) A mask oxide film 9 is formed on selected areas by chemical vapour deposition. Using it as a mask, a P-type impurity such as boron is ion-implanted, whereby P-type regions 10 to become the sources and 15 drains of P-channel MOSFETs and P-type polycrystalline silicon layers 11 are formed. Here, in case of using boron, the oxide film 9 is made about 3,000 Å thick, and an implantation energy of 30 to 50 keV and an implantation quantity of 2×10^{15} to $1 \times 10^{16} \text{ cm}^{-2}$ may be used. The activation of the implanted ions may be 15 achieved by a heat treatment ranging from 900°C for 10 minutes to 1,000°C for 30 minutes. 15

The diffusion of the N-type impurity in the step (b) may be performed after the step (c). In this case, the N-type impurity diffusion indicated in the step (b) is preferably performed by the ion implantation of phosphorus or a similar substance. In the case of using phosphorus, the oxide film 6 is made about 3,000 Å 20 thick, and an implantation energy of 60 to 100 keV and an implantation quantity of 2×10^{15} to $1 \times 10^{16} \text{ cm}^{-2}$ 20 are appropriate. A heat treatment suitable for the activation of the implanted ions is at 900°C for 10 minutes to at 1,000°C for 30 minutes. By carrying out the doping with the P-type impurity in this manner, the heat treatment after the doping with the P-type impurity can be eliminated, so that the channel portions can be prevented from being doped with the P-type impurity. 25

(d) After depositing a phosphosilicate glass film 12 by the chemical vapour deposition, contact holes are 25 formed, and aluminium electrodes 13 are formed, the device is then complete.

Referring again to Figure 58, another embodiment of the present invention will now be described. In the Figure, a P-channel MOSFET Q₁ has a gate electrode made of N-type polycrystalline silicon 6', and a P-channel MOSFET Q₂ has a gate electrode made of P-type polycrystalline silicon 6.

Since these FETs are manufactured under substantially the same conditions except for the conductivity 30 types of the gate electrodes, the difference of the threshold voltages V_{th} of both the FETs becomes substantially equal to the difference of the Fermi levels of the P-type silicon and the N-type silicon. The gate electrodes are doped with respective impurities near the saturation densities, and the difference becomes substantially equal to the energy gap E_g of silicon (approximately 1.1 V). The V_{th}-difference can be obtained 35 with high precision by making the channel dimensions of both the FETs equal, and it is utilized as a reference 35 voltage source.

Since a reference voltage generating device based on such a construction exhibits a small temperature-dependence and small manufacturing variations, it can be used for various electronic circuits.

In Figure 58, is shown an N-type silicon body 1, a thick field oxide film 1, a gate oxide film 2, a P-type source 40 region 4, and a P-type drain region 5. Here, the N-type polycrystalline silicon gate 6' has a structure which is doped with both an N-type impurity and a P-type impurity, the density of the N-type impurity being 1.5 times or more higher than the density of the P-type impurity. Alternatively, it has a structure which is doped with an N-type impurity, almost no P-type impurity being contained, and nevertheless, which is self-aligned with the source and drain. 40

The reason why the density of the N-type impurity needs to be 1.5 times or more higher than the density of the P-type impurity is as follows. In the ordinary high-density impurity doping techniques, the control of a density is subject to variations of about $\pm 20\%$ of the set value. Hence, the ratio between the variations of the N-type impurity density and the P-type impurity density becomes $(1.5 \pm 0.3)/(1.1 \pm 0.2)$. Since the minimum value of this ratio becomes 1/1, the Fermi level of the polycrystalline silicon doped with both the N-type and 50 P-type impurities varies greatly. 45

In order to allow some manufacturing variation, the ratio of the impurity densities needs to be always 1.5 or greater.

Figures 82(a) and 82(b) illustrate a method of manufacturing IGFETs for setting the ratio of the impurity densities at 1.5 or greater. The method has stages as described below.

(a) An N-type silicon body 1 at a comparatively low impurity density (for example, below $5 \times 10^{16} \text{ cm}^{-3}$) 55 is oxidized to form a thick oxide film 2 for isolating elements. After forming a gate oxide film 3 in recesses of the film 2, an intrinsic semiconductor polycrystalline silicon film at 6 and 6' is deposited by chemical vapour deposition. Then, a mask oxide film 7 is formed on a selected area by chemical vapour deposition. Using the oxide film 7 as a mask, the polycrystalline silicon film 6' is selectively doped with an N-type impurity such as phosphorus or arsenic and at a high density (for example, above $5 \times 10^{18} \text{ cm}^{-3}$). Thus, the N-type 60 polycrystalline silicon film 6' is obtained. 60

(b) After removing the mask oxide film 7, the working of a polycrystalline silicon gate electrode is performed by photoetching, and source and drain impurity layers 4 and 5 are formed at a low density (for example, below $3.3 \times 10^{18} \text{ cm}^{-3}$) by the thermal diffusion of a P-type impurity such as boron. Here, the 65 density of the N-type impurity with which the polycrystalline film 6' is doped in the stage (a) is made 1.5 65

times or more higher than the density of the P-type impurity with which the polycrystalline silicon film 6' is doped at the time of the P-type impurity diffusion in the stage (b), and hence the polycrystalline silicon gate 6' is held at the N-type.

Figures 83(a) to 83(d) illustrate another method of manufacture according to this invention. Figure 83(a) shows the same manufacturing step as in Figure 82(a). The subsequent stages are described below.

(b) After removing the mask oxide film 7, the processing of a polycrystalline silicon gate electrode is performed by photoetching. Subsequently, using the polycrystalline silicon gates 6 and 6' as a mask, the gate oxide film, which lies on parts corresponding to sources and drains to be formed, is removed, the resultant silicon body is then subjected to an oxidation in steam at 750°C to 900°C for 60 seconds to 600 seconds. In the oxidation, the oxide film-growth rate of the silicon surface depends upon the density of an impurity contained in the silicon. Especially when the impurity density is at least $5 \times 10^{18} \text{ cm}^{-3}$, preferably 10^{20} cm^{-3} or higher, the oxide film-growth rate becomes large. Therefore, comparatively thin oxide films 8 and 10 of 20 to 40 Å are formed on the surfaces of the parts corresponding to the source and drain and having the comparatively low impurity density and on the surface of the intrinsic polycrystalline silicon 6, respectively. Also, a comparatively thick oxide film 9 of 70 to 200 Å is formed on the surface of the N-type polycrystalline silicon gate 6' having the comparatively high impurity density.

(c) Boron can pass through an oxide film of a thickness of at most 40 Å by thermal diffusion, and cannot pass through an oxide film of a thickness of at least 70 Å. Therefore, boron is subsequently thermally diffused at 950 to 1,000°C for about 20 minutes. Thus, the boron penetrate through the comparatively thin oxide films 8 and 10 to form the P-type impurity layers 4 and 5 and the P-type polycrystalline silicon layer 6. At this time, the N-type polycrystalline silicon layer 6' is protected by the comparatively thick oxide film 9, and it is not doped with the boron. As an alternative method, the oxide films are etched with an etchant of HF : H₂O = 1 : 99 to 60 seconds before the thermal diffusion of boron to remove the oxide films 8 and 10 and to leave the oxide film 9 with a thickness of 40 - 150 Å. Thermal diffusion of boron is then performed. Thus, a similar structure is obtained.

(d) Subsequently, a phosphosilicate glass film 11 is formed, contact holes are formed, and aluminium electrodes 12 are formed. The fabrication of the device is then complete.

Although the present method of manufacture has been explained referring to the example of silicon gate P-channel MOSFETs, the same method applies in the case of P-channel MOSFETs in a silicon gate CMOSIC. Circuits according to embodiments of the present invention for obtaining the difference of the threshold voltages V_{th} of the MOS transistors will now be explained.

Although the circuits described below can be used to obtain the differences of the Fermi levels ($E_{fn} - E_{fp}$), ($E_{fn} - E_i$) and ($E_i - E_{fp}$), they are further applicable as reference voltage generating devices which, in general utilize as a reference voltage a voltage based on the difference of the threshold voltages V_{th} of FETs having unequal threshold voltage values.

Figure 6(b) shows a circuit which generates voltages corresponding to threshold voltages of MOS transistors. Transistors T₁ and T₂ form the so-called MOS diodes in which drains and gates are connected together.

I_0 designates a constant-current source, and T₁ and T₂ indicate MOSFETs which have unequal threshold voltages V_{th1} and V_{th2} as indicated in Figure 6(a) and substantially equal mutual conductances β . Letting the drain voltages of the respective transistors be V₁ and V₂, the following equations hold;

$$\begin{aligned} I_0 &= 1/2 \beta (V_1 - V_{th1})^2 \\ 45 &= 1/2 \beta (V_2 - V_{th2})^2 \end{aligned} \quad \dots (21)$$

Therefore,

$$\begin{aligned} V_1 &= V_{th1} + \sqrt{2 I_0 / \beta} \\ 50 &V_2 = V_{th2} + \sqrt{2 I_0 / \beta} \end{aligned} \quad \dots (22)$$

By taking the difference of the drain voltages, the difference of the threshold voltages can be derived. Sufficiently high resistances may be used as the constant-current source. If their characteristics are uniform, there can be used diffusion resistances, polycrystalline Si resistances, resistances formed by the ion implantation, or high resistances formed from MOS transistors.

When, in this circuit, the N⁺ gate P-channel MOS and the P⁺ gate P-channel MOS, previously explained with reference to Figures 58 and 59 respectively, are used as the transistors T₁ and T₂, that difference ($E_{fn} - E_{fp}$) of the Fermi levels of the N-type semiconductor and the P-type semiconductor which is a value substantially equal to the difference of the threshold voltages can be obtained.

In addition to making the compositions of the gate electrodes different, it is possible to create unequal

threshold voltages by, for example, implanting ions into the channels, altering the thicknesses of a doped gate oxide or gate insulating films, etc. When such a measure is applied to the circuit of Figure 6(b), the difference of the threshold voltages, corresponding to the implanted quantities of the ions or the difference of threshold voltages, corresponding to the quantities of an impurity with which the gate insulating films are 5 doped, or corresponding to the thicknesses of the gate insulating films, can be similarly obtained as the reference voltage.

For example, the ion implantation method can achieve a higher precision of impurity concentration than the conventional diffusion because the quantity of implantation can be monitored in the form of current.

Figure 7 illustrates this situation. Letting T_1 denote the characteristics of MOS transistors before the 10 implantation of ions, if they have been individually dispersed at the manufacture and the threshold values are individually shifted by ΔV_{th} due to the ion implantation, the magnitude ΔV_{th} , being the difference of both the threshold voltages, is determined by the quantity of the ion implantation and therefore only varies to a small extent. It can accordingly be similarly used as a reference voltage with only small variations of manufacture. More specifically, letting V_{th1} indicate the threshold voltage of the MOS transistor T_1 , which is 15 not subjected to the ion implantation, similarly to Equation (15):

$$V_{th1} = \phi_{MS} - 2\phi_F - \frac{Q_{ss}}{COX} - \frac{Q_B}{COX} \quad \dots (23)$$

20 Letting ΔQ_B indicate the increment of fixed changes in the substrate due to the ion implantation, the threshold voltage V_{th2} of the MOS transistor T_2 subjected to the ion implantation becomes:

$$V_{th2} = \phi_{MS} - 2\phi_F - \frac{Q_{ss}}{COX} - \frac{Q_B + \Delta Q_B}{COX} \quad \dots (24)$$

30 Thus

$$35 \quad V_{th1} - V_{th2} = \frac{\Delta Q_B}{COX} \quad \dots (25) \quad 35$$

The temperature variation of this difference voltage between the threshold voltages is extremely small because Q_B is almost invariable under temperature changes.

40 Also advantageous is that the reference voltage can be freely set by the quantity of ion implantation and that the device can be easily constructed, even by the single-channel MOS manufacturing process.

Figures 8 and 9 show examples of circuits in which an N^+ -gate and FET T_1 and a P^+ -gate FET T_2 having unequal threshold voltages, as in the case of Figures 6(a) and 6(b), are used, and the FET T_1 is connected in the MOS diode form and is connected in series with the FET T_2 , to obtain the difference of the threshold 45 voltages. It is supposed that the FET T_1 has a threshold voltage V_{th1} , while the FET T_2 has a threshold voltage V_{th2} .

Under the condition that the resistance R_1 is sufficiently large when compared with the impedance of T_1 , and that the resistance R_2 is sufficiently large when compared with the impedance of T_2 ,

$$50 \quad V_1 - V_2 \approx V_{th1} \quad \dots (26) \quad 50$$

$$55 \quad V_1 \approx V_{th2} \quad \dots (27) \quad 55$$

Therefore,

$$60 \quad V_2 \approx V_{th1} - V_{th2} \quad \dots (28) \quad 60$$

Figure 11(a) shows a device in which voltages corresponding to the threshold voltages of an N^+ -gate MOS T_1 and a P^+ -gate MOS T_2 are applied to both terminals of a capacitor C_1 connected to the MOS transistors, 65 and a voltage across the capacitor is obtained as a difference voltage. Figure 11(b) shows the operating

timings. MOS FETs T₅ and T₆ are turned "on" by a clock pulse ϕ_1 , to charge the difference voltage of the threshold voltages V_{th1} and V_{th2} of the MOS FET T₁ and T₂ in a capacitor C₁.

After turning the MOS FETs T₅ and T₆ "off" by the pulse ϕ_1 , a MOS FET T₃ is turned "on" by a clock ϕ_2 so as to ground a node ① of the capacitor C₁. Since, at this time, the difference voltage of the threshold voltages is stored in the capacitor C₁, the difference potential appears at a node ② of the capacitor C₁ unchanged. In the case of use for a voltage detector circuit to be described later, the potential of the node ② at this time can be employed as a reference voltage. In order to permit the use in a more general form, however, transmission gates T₆ and T₇ are turned "on" by a clock ϕ_3 within a period of time during which the high level signal of the clock ϕ_2 is applied, the potential is stored across a capacitor C₂ connected to the non-inverting input (+) of an operational amplifier 5, and the potential is received by the voltage follower in which 100 % of an output is negatively fed back to the inverting input (-) of the operating amplifier 5. Then, the output of the voltage follower, the difference of the threshold voltages of T₁ and T₂, is obtained as a reference voltage when the internal impedance is sufficiently low.

Figure 10(a) is a circuit diagram showing an embodiment of a dynamic type difference voltage output circuit which uses the difference of the threshold voltages of an N⁺-gate N-channel MOS Q₁ and a P⁺-gate N-channel MOS Q₂.

In this circuit, the gates and drains of the MISFETs Q₁, Q₂ are interconnected, and they are connected to a bias power supply -V_{DD} through load resistors (R₁, R₂). A capacitor C is situated between the gate and drain terminals, and the difference component between the threshold voltages of the MISFETs Q₁, Q₂ is stored in the capacitor so as to provide an output. A P-channel MISFET Q₃ which is driven by a clock pulse ϕ is incorporated between the gate and source of the MISFET Q₁ with smaller threshold voltage. The respective load resistances of the MISFETs Q₁, Q₂, and on the "on" resistance of the MISFET Q₃ is made sufficiently smaller than the "on" resistances of the MISFETs Q₁, Q₂. In such a circuit arrangement, as shown in an operating waveform diagram of Figure 10(b), when the clock pulse ϕ has reached a low level, to turn the MISFET Q₃ "on", the difference -(V₂ - V₁) between the drain voltages (threshold voltages V₁, V₂) of both the MISFETs Q₁, Q₂ is provided from the drain of the MISFET Q₂ or the terminal of the capacitor C remote from the MISFET Q₃. The difference voltage output similar to those of the foregoing circuits is obtained by sampling it at a pulse time ϕ .

Figure 12 shows a reference voltage generating device which utilizes an N⁺-gate MOS T₁, a P⁺-gate MOS T₂ and a capacitance C₂ in a similar way. A MOS FET T₈ is turned "on" by a clock ϕ_1 . At this time, a MOS FET T₉ is in the "off" state due to the output of a clock ϕ_2 . The potential of a node ⑥ becomes lower than that of a node ⑤ by the threshold voltage V_{th1} of the MOS FET T₁, and the potential of a node ⑦ becomes lower than that of the node ⑥ by the threshold voltage V_{th2} of the MOS FET T₂. Hence, the difference voltage of both the threshold voltages V_{th1} and V_{th2} is applied across the capacitance C₂. Subsequently, the MOS FET T₈ is turned "off" by ϕ_1 and the MOS FET T₉ is turned "on" by ϕ_2 . Then, the difference voltage of the threshold voltages is provided at the node ⑦.

Figure 13 shows an operational amplifier according to the present invention. A differential pair T₁ and T₂ constitute a differential amplifier circuit, and T₁₂ and T₁₃ designate active loads of the differential amplifier. A transistor T₁₁ forms a constant-current circuit with transistors T₁₄ and T₁₆. Transistors T₁₅ and T₁₆ form a level shift output buffer circuit whose constant-current source load is the transistor T₁₆. Although the example of a circuit arrangement based on C-MOS is shown in the Figure, the circuit can of course be constructed of single-channel MOS.

In this operational amplifier, the differential pair transistors T₁ and T₂ forming the differential amplifier circuit are provided with unequal threshold voltages V_{th1} and V_{th2} on the basis of the Fermi level difference of the gate electrodes as described previously, the difference of the threshold voltages can be utilized or obtained as a reference voltage. This is a new application of an operational amplifier.

Figure 14 shows schematically an ordinary operational amplifier, showing only the features that make it a differential amplifier. It is here assumed that MOS transistors T₁ and T₂ have unequal threshold voltages V_{th1} and V_{th2} respectively and that the other characteristics such as mutual conductances are equal. Signs (-) and (+) appearing on the input side signify the inverting and non-inverting inputs, respectively.

Letting V₁ denote an input voltage of the transistor T₁ and V₂ an input voltage of the transistor T₂,

$$V_1 - V_{th1} = V_2 - V_{th2}$$

that is,

$$V_1 - V_2 = V_{th1} - V_{th2} \quad \dots (29)$$

The output level changes with this input voltage condition as the boundary.

The operational amplifier is provided with an input offset corresponding to the difference voltage of the threshold voltages. Therefore, when either the inverting input (-) or the non-inverting input (+) is earthed or

connected to a reference potential of a power supply, it can be operated as a voltage comparator whose reference voltage is the offset voltage. Alternatively, when the output is connected to the inverting input terminal (-) to construct a voltage follower circuit and the non-inverting input terminal (+) is earthed as shown in Figure 14, the difference of the threshold voltages is obtained at the output 'Out'. In this example, in order to operate the operational amplifier, the transistor T₂ needs to be a depletion mode MOS FET. For example, if a P⁺-gate MOS is used for T₁ and an N⁺-gate MOS is used for T₂, they may be made the depletion type by subjecting the channel portions of both the MOSFETs to the ion implantation under the same conditions.

Figure 15 shows a device which can arbitrarily set a reference voltage by the use of the operational amplifier in Figure 14. An output is fed back to the inverting input (-) through voltage divider means R₅ and R₆. Thus, letting r denote the voltage division ratio R₆/R₅+R₆, the output voltage V_o becomes:

$$15 \quad V_o = \frac{V_{th1} - V_{th2}}{r} \quad \dots\ (30) \quad 15$$

The voltage divider means R₅ and R₆ should preferably be linear resistances, but any resistances may be adopted provided that their characteristics are sufficiently uniform.

The circuits of Figures 14 and 15 assume the use of the depletion type MOS, but the circuits in Figures 16 and 17 operate with enhancement type MOS. Of course, the depletion type MOS may be used.

Similarly, to the example of Figure 14, the example of Figure 16 directly feeds an output back to an inverting input (-). Letting V_{DD} denote a supply voltage, the output V_o becomes:

25

$$V_o = V_{DD} - (V_{th1} - V_{th2}) \quad \dots\ (31)$$

30 With the circuits of Figures 14 and 15, at least one of the differential pair transistors needs to be put into the depletion mode, which necessitates an increase in the number of manufacturing steps in some cases. However, they can obtain the difference voltage of the threshold voltage V_{th} with reference to the earth potential.

Conversely, with the circuits of Figures 16 and 17 the reference of the difference voltage to be obtained is not the earth potential. However, the condition of the operating mode of the FET is not imposed.

The circuit form which is adopted may be decided by the feature to which most importance is attached.

Similarly to the example of Figure 15, the example of Figure 17 feeds an output back to an inverting input (-) through voltage divider means R₇ and R₈. The output becomes:

40

$$V_o = V_{DD} - \frac{V_{th1} - V_{th2}}{r} \quad \dots\ (32)$$

45 Figure 18 shows a voltage detector circuit in which a reference voltage V_R from a reference voltage generating device RVG according to the present invention, which uses the difference of the threshold voltages V_{th}, is applied to one input of a conventional voltage comparator VC and a voltage V_D to be detected is applied to the other input, the height of the voltage to-be-detected V_D relative to the reference voltage V_R can hence be discriminated.

50 Shown as an example in Figure 19 is a voltage detector circuit wherein a reference voltage V_R from a reference voltage generating device RVG which utilizes the difference of threshold voltages V_{th}, corresponding to the Fermi level difference of gate electrodes in accordance with the present invention, is applied to one input of a voltage comparator VC and a voltage obtained by dividing a voltage to-be-detected V_D by voltage divider means R₉ and R₁₀, is applied to the other input. Letting r denote the voltage division ratio, V_{ref} denote the reference voltage and V_{sense} the detection level.

55

$$V_{sense} = \frac{V_{ref}}{r} \quad \dots\ (33)$$

60 The detection level V_{sense} can be arbitrarily set by controlling the voltage division ratio r.

Shown, as an example, in Figure 20 is a voltage detector circuit which uses the operational amplifier with the offset corresponding to the difference of the threshold voltages V_{th} as described with reference to Figure 13 and uses the offset voltage as a reference voltage as explained previously. R₁₁ and R₁₂ indicate voltage divider means similarly to the example of Figure 19.

40

45

50

55

60

65

If the voltage to-be-detected V_D is a battery supply voltage, in the example of Figure 18, 19 or 20, the voltage detector circuit can be used as a battery checker in a system which uses a battery as a power supply. An example in which the voltage detector circuit of Figure 20 is applied to the battery checker of an electronic timepiece is shown in Figure 54, and will be described in detail later.

5 Figure 21 shows another embodiment of an operational amplifier circuit which is constructed by connecting, in the differential form, N-channel MOS FETs Q_1 and Q_2 having unequal threshold voltages V_{th} on the basis of the difference of the Fermi levels of gate electrodes in accordance with the present invention. MOS FETs Q_3 and Q_4 operate as load FETs of the differential pair of MOS FETs Q_1 and Q_2 , and a MOS FET Q_5 operates as a constant-current source of the differential pair of MOS FETs Q_1 and Q_2 .

10 Figure 22 shows a differential amplifier circuit which has as its offset voltage, the difference of the threshold voltages V_{th} of MOS transistors Q_1 and Q_2 according to the present invention. 10

Figure 23 shows the drain current-versus-gate voltage characteristics of the MOS transistors Q_1 and Q_2 in Figure 22.

In this embodiment, the mutual conductances of the MOS transistors Q_1 and Q_2 constituting the differential pair are designed so as to become equal. As the current of a constant-current source CS of the differential circuit changes to be I_o , I_o' and I_o'' , their points of intersection with the $V_{GS} - \sqrt{I_{DS}}$ characteristic of the transistor Q_1 vary to be points 1, 1' and 1'' respectively, and their points of intersection with the $V_{GS} - \sqrt{I_{DS}}$ characteristics of the transistor Q_2 vary to be points 2, 2' and 2'' respectively. Initially, voltages V_{G1} and V_{G2} are applied to the gates of the respective transistors Q_1 and Q_2 in order to bring the differential circuit 15 into the balanced state. Hence, even when the current of the constant-current source CS has changed from I_o to I_o' or I_o'' in dependence on the temperature, the difference of the voltages V_{G1} and V_{G2} which balance the differential circuit are held substantially constant. The difference voltage reflects the difference ($V_{th1} - V_{th2}$) of the threshold voltages of the transistors Q_1 and Q_2 . Hence, the temperature characteristic of the difference ($V_{th1} - V_{th2}$) of the threshold voltages of the transistors Q_1 and Q_2 appears unchanged as the difference ($V_{G1} - 20 V_{G2}$) of the voltages to be applied to the gates of the transistors Q_1 and Q_2 in order to put these transistors 20 into the balanced state. 20

When the P⁺-gate and N⁺-gate N-channel MOS transistors previously described are used as the transistors Q_1 and Q_2 respectively, a voltage of approximately 1.1 V corresponding to the band gap is obtained. In the case of using a silicon semiconductor, this difference voltage has a temperature dependence with a gradient 30 of -0.24 mV K^{-1} . 30

The temperature dependence of the difference voltage of the gate voltages can be nullified by making the values of the conductances of the transistors Q_1 and Q_2 unequal.

Suppose, for example, that the temperature dependence of the constant-current source CS of the differential circuit has a positive gradient, while the difference ($V_{th1} - V_{th2}$) of the threshold voltages of the transistors Q_1 and Q_2 exhibits a temperature dependence with a negative gradient. As indicated at Q_1 and Q_2 in Figure 23, the conductance of the transistor Q_2 is made smaller than the conductance of the transistor Q_1 , hence, the gate voltage of the transistor Q_2 under the balanced state varies as indicated at 3, 3' and 3'' in dependence on the temperature, and the temperature dependence of the difference of the gate voltages of the transistors Q_1 and Q_2 as based on the difference of the conductances of the transistors Q_1 and Q_2 has a 35 positive gradient. By suitably combining the magnitudes of the conductances, the total temperature dependence can be made zero or, at least, can be improved. 40

In the case where the temperature dependence of the constant-current source of the differential circuit has a negative gradient, the conductance of the transistor Q_2 is made greater than the conductance of the transistor Q_1 , conversely to the above, and hence the temperature dependency can be improved.

45 In the balanced state, the following relations hold between the current I_o of the constant-current source, and the threshold voltages V_{th1} and V_{th2} , mutual conductances β_1 and β_2 and gate voltages V_{G1} and V_{G2} of the respective transistors Q_1 and Q_2 : 45

$$50 I_o = \frac{\beta_1}{2} (V_{G1} - V_{th1})^2 = \frac{\beta_2}{2} (V_{G2} - V_{th2})^2 \quad \dots (34) \quad 50$$

$$55 V_{G1} = V_{th1} + \sqrt{2I_o/\beta_1} \quad \dots (35) \quad 55$$

$$V_{G2} = V_{th2} + \sqrt{2I_o/\beta_2} \quad \dots (36)$$

$$60 V_{G1} - V_{G2} = (V_{th1} - V_{th2}) + \sqrt{2I_o} \left(\frac{1}{\sqrt{\beta_1}} - \frac{1}{\sqrt{\beta_2}} \right) \quad \dots (37) \quad 60$$

In Equation (37), when $\beta_1 > \beta_2$, $\frac{1}{\beta_1} - \frac{1}{\beta_2} < 0$, and when $\beta_1 < \beta_2$, $\frac{1}{\beta_1} - \frac{1}{\beta_2} > 0$.

5 Therefore, the temperature gradient of the second term of Equation (37) can become either positive or negative.

Figures 24 and 25 show application circuits of voltage comparators each being another embodiment which can reduce the temperature dependence on the basis of the concept described above.

10 In Figure 24, MOS FETs Q₁ and Q₂ whose threshold voltages V_{th} are unequal owing to the difference of the Fermi levels of gate electrodes in accordance with the present invention are operated as source followers.

The balanced state corresponds to the time when the differential input voltage of a voltage comparator circuit or operational amplifier circuit CMP₁ is zero. In the balanced state, the following relations hold between the threshold voltages V_{th1} and V_{th2}, mutual conductances β₁ and β₂, gate voltages V_{G1} and V_{G2}, source voltages V₁ and V₂ and drain currents I₁ and I₂ of the respective MOS FETs Q₁ and Q₂:

15

$$I_1 = \frac{1}{2}\beta_1(V_{G1} - V_{th1} - V_1)^2$$

20

$$I_2 = \frac{1}{2}\beta_2(V_{G2} - V_{th2} - V_2)^2 \quad \dots (38)$$

$$V_1 = V_2 \quad \dots (39)$$

25

Hence,

$$V_{G1} = V_{th1} + V_1 + \sqrt{2I_1/\beta_1} \quad \dots (40)$$

30

$$V_{G2} = V_{th2} + V_2 + \sqrt{2I_2/\beta_2} \quad \dots (41)$$

35

$$V_{G1} - V_{G2} = (V_{th1} - V_{th2}) = (\sqrt{2I_1/\beta_1} - \sqrt{2I_2/\beta_2}) \quad \dots (42)$$

Thus, assuming that I₁ = I₂ = I, the temperature dependency of (V_{G1} - V_{G2}) can be made zero by appropriately setting β₁ and β₂ to conform with the temperature dependence of I and the temperature dependence of (V_{th1} - V_{th2}) similarly to the case of the differential circuit.

Further, in this example of the circuit, assuming that β₁ = β₂ = β, Equation (42) becomes:

45

$$V_{G1} - V_{G2} = V_{th1} - V_{th2} + \sqrt{2/\beta} (\sqrt{I_1} - \sqrt{I_2}) \quad \dots (43)$$

45

Therefore, even when the currents I₁ and I₂ are set at unequal values, the temperature dependence of the difference (V_{G1} - V_{G2}) can be similarly made zero.

Figure 26 shows an embodiment of a constant-current circuit. When the conductances of FETs Q₂ and Q₃ are made 1 : n, a current flowing through the FET Q₃ can be made n.I relative to a current I flowing through FETs Q₁ and Q₂.

Accordingly, I₁ and I₂ in Equation (43) can be readily achieved by changing the ratio n in the above constant-current circuit.

Figure 27 shows an embodiment of a reference voltage generating circuit based on the differential circuit of Figure 22.

Transistors Q₁, Q₂, Q₃ and Q₉ enclosed with dotted lines in Figure 27 form a constant-current circuit similar to that in Figure 26, while transistors Q₄, Q₅, Q₆, Q₇ and Q₈ form a differential circuit similar to that in Figure 22. The transistor Q₆ is a P⁺-gate N-channel MOS transistor, and the transistor Q₇ is an N⁺-gate N-channel MOS transistor.

60 Arrow symbols of gates represent the N⁺-gate and the P⁺-gate discriminately.

The MOS transistors Q₆ and Q₇ have their threshold voltages shifted by equal values by means of ion implantation or a similar process, and the MOS transistor Q₇ is a depletion MOS transistor.

60

55

55

An output based on transistors Q_6 and Q_7 is negatively fed back to the gate of the transistor Q_6 . For an output voltage, the offset voltage of the transistors Q_6 and Q_7 can be used as a reference voltage. Letting V_o denote the output voltage and letting in Equation (37)

$V_{G1} = V_o, V_{G2} = 0, V_{th1} = V_{thn} +, V_{th2} = V_{thp} +, \beta_1 = \beta_6$ and $\beta_2 = \beta_7$, then:

5

5

$$V_o = V_{thn} + - V_{thp} + + \sqrt{2} I_o \left(\frac{1}{\sqrt{\beta_6}} - \frac{1}{\sqrt{\beta_7}} \right) \quad \dots \dots (44)$$

10

10

In this case, $(V_{th1} - V_{th2})$ is the difference between the threshold voltages of the P^+ -gate N-channel MOS transistor and the N^+ -gate N-channel MOS transistor and become substantially equal to the band gap voltage of 1.1 V. The output voltage V_o is formed by adding the correction voltage of the second term to the band gap voltage.

Letting the mutual conductance of the transistor Q_1 be β_1 , and supposing the drain voltage of the transistor Q_2 to be substantially equal to the threshold voltage V_{thn}

20

20

$$I_o = \beta_1 [(V_{DD} - V_{thn})(V_{DD} - V_{thp}) - \frac{1}{2}(V_{DD} - V_{thp})^2] \quad \dots \dots (45)$$

25 In addition,

25

$$\beta_1 = \beta_{OP} (W/L)_1$$

$$30 \quad \beta_6 = \beta_{ON} (W/L)_6, \quad \beta_7 = \beta_{ON} (W/L)_7$$

30

where

β_{OP} and β_{ON} denote the mutual conductances per unit area of the N-MOS and P-MOS transistors, respectively. Hence, the output voltage is given by the equation

35

40

40

$$V_o = V_{thn} + - V_{thp} + + \sqrt{\frac{\beta_{OP}}{\beta_{ON}}} \cdot \sqrt{(W/L)_1} \cdot$$

45

45

$$\times [(V_{DD} - V_{thn})(V_{DD} - V_{thp}) - \frac{1}{2}(V_{DD} - V_{thp})^2] \quad \dots \dots (46)$$

Differentiating Equation (46) as to the temperature T ,

50

50

$$\frac{\delta V_o}{\delta T} = \frac{\delta}{\delta T} (V_{thn} + - V_{thp} +) + \sqrt{\frac{\beta_{OP}}{\beta_{ON}}} \cdot$$

55

55

$$\sqrt{(W/L)_1} \cdot \sqrt{\frac{(W/L)_7 - \sqrt{(W/L)_6}}{(W/L)_6 (W/L)_7}} \cdot$$

60

60

$$\times \frac{\delta}{\delta T} [(V_{DD} - V_{thn})(V_{DD} - V_{thp}) - \frac{1}{2}(V_{DD} - V_{thp})^2] \quad \dots \dots (47)$$

65 $(W/L)_6$ and $(W/L)_7$ can be set so that the condition $\frac{\delta V_o}{\delta T} = 0$ may be achieved.

65

Figure 28 shows an embodiment of a reference voltage generating circuit which is based on the construction of Figure 24. A circuit within dotted lines in Figure 28 forms the comparator circuit CMP_1 shown in Figure 24.

Transistors Q_1 , Q_2 , Q_4 and Q_6 constitute a constant-current circuit. Currents flowing through transistors Q_3 5 and Q_5 can also be made unequal by making the ratios of the conductances of the transistors Q_4 and Q_6 different relative to the conductance of the transistor Q_2 .

In this example the transistors Q_3 and Q_5 are an N^+ -gate N-channel MOS transistor and a P^+ -gate N-channel MOS transistor respectively.

As in previous examples, the output voltage V_o is negatively fed back to the gate of the transistor Q_3 so as 10 to construct the voltage follower, and the earth potential is applied to the transistor Q_5 .

The temperature dependence of the output voltage can be made zero by making the conductances of the transistors Q_3 and Q_5 or the conductances of the transistors Q_4 and Q_6 unequal in accordance with Equation (42) or (43), or by combining both these measures.

Suppose, for example that the conductances of the transistors Q_3 and Q_5 are equal at β , that the current to 15 flow through the transistor Q_1 is I_o , and that the ratio of the conductances of the transistors Q_2 and Q_4 is $1:n$, while the ratio of the conductances of the transistors Q_6 and Q_5 is $1:n'$. Then, the output voltage V_o becomes:

$$20 \quad V_o = V_{thn}+ - V_{thp}+ + \sqrt{\frac{2}{\beta}} \frac{I_o}{(\sqrt{n'} - \sqrt{n})} \quad (48) \quad 20$$

25 By adjusting the values of n' and n , the temperature dependence of the output voltage V_o can be made substantially zero. As a circuit arrangement which generates a reference voltage and which can make zero or improve the temperature dependency of the reference voltage, the circuit arrangement shown in Figure 25 may be used or circuit arrangements described previously. This circuit is operated with the sources of transistors Q_1 and Q_2 earthed.

30 Figure 29 shows an embodiment of a circuit having a constant current which is determined by the difference of the threshold voltages of MOS FETs T_1 and T_2 in accordance with the present invention.

The MOS FETs T_1 and T_2 have equal mutual conductances β , and their threshold voltages have values V_{th1} and V_{th2} different from each other due to the difference between the Fermi levels of gate electrodes in accordance with the present invention. If a resistance R_{20} is sufficiently high, when compared with the 35 impedance of T_1 , the drain voltage (= gate voltage) V_1 of T_1 becomes substantially equal to V_{th1} .

When T_2 is in the saturation region, the current I_2 flowing through T_2 is:

$$40 \quad I_{out} = \frac{1}{2}(V_{th1} - V_{th2})^2 \quad (49) \quad 40$$

45 Shown in Figure 30 is an embodiment of a constant-current circuit employing a reference voltage generating device RVG which generates a reference voltage V_{REF} ($= V_{th1} - V_{th2}$) determined by the difference voltage of the threshold voltages of MOS FETs corresponding to the difference between the Fermi levels of the gate electrodes in accordance with the present invention, and an ordinary operational amplifier VC . In the 45 constant-current circuit, a voltage drop $I_{out}R_{21}$ based on a current I flowing through a MOS FET T_{22} is compared with a reference voltage V_{REF} , and the gate voltage of T_1 is controlled so that both may be equal at all times.

50 From

$$55 \quad I_{out}R_{21} = V_{REF} \quad (50) \quad 55$$

$$I_{out} = \frac{V_{REF}}{R}$$

60 In this case, the reference voltage may be obtained by providing the operational amplifier VC with an offset and earthing the non-inverting input (+) of the operational amplifier VC as in the previous example in Figures 13 and 14.

Figure 31 shows an embodiment of a constant-current circuit wherein the so-called current mirror circuit in which MOS transistors T_{31} and T_{33} have the same characteristics.

65 Figure 32 shows an example of an application in which a reference voltage V_{REF} which is determined by the difference voltage of the threshold voltages of MOSFETs corresponding to the difference of the Fermi levels

of the gate electrodes of the MOS FETs in accordance with the present invention is used for a stabilized power supply circuit. A reference voltage generating device RVG is constructed by any of the above-stated several methods according to the principle of the present invention. A divided voltage of a stabilized output due to voltage divider means R_{13} and R_{14} and a reference voltage are compared, and the gate voltage of a 5 controlling MOSFET T_{20} is controlled so as to bring them into agreement, to stabilize the output voltage V_{out} . Any operational amplifier may be used provided that its characteristics are suitable.

In an embodiment shown in Figure 33, the MOS transistor used for T_{20} in the example of Figure 32 is replaced with a bipolar transistor TR_1 .

The embodiment shown in Figure 34 uses the operational amplifier VC as shown in the example of Figures 10 13 and 14, which has the offset voltage based on the difference voltage of the threshold voltage V_{th} of MOSFETs and whose non-inverting input (+) is earthed. T_{21} may be a MOS transistor, a bipolar transistor or a junction field-effect transistor.

Figure 35(a) shows a voltage regulator according to the present invention which is a further improvement on the stabilized power supply circuits illustrated in Figures 32, 33 and 34, and Figure 35(b) is a characteristic 15 diagram of the voltage regulator.

The circuit arrangement in Figure 35(a) is constructed as a comparing voltage regulator. It differs from a conventional voltage comparator in that the input characteristics of an operational amplifier VC being a voltage comparator are asymmetric at the input terminals of a non-inverting input (+) and an inverting input (-). Thus, this voltage comparator does not balance when the voltage levels of the non-inverting input (+) 20 and the inverting input (-) are equal to each other, but balances when a predetermined high input voltage (in the absolute value) is applied on the inverting input (-). Hence, in this voltage comparator, the input levels of the non-inverting input (+) and the inverting input (-) have an offset with respect to the balance point.

Alternatively, in a conventional voltage regulating where the input voltage V_{in} is high, the output voltage V_{out} depends upon a reference voltage V_{ref} generated from the reference voltage generator RVC and the 25 difference of $V_{out} - V_{in}$ is made large, whereas in the case where the input voltage V_{in} is low, V_{out} depends solely upon V_{in} and the difference of $|V_{in} - V_{out}|$ is made small. According to the present invention, the changing point P between both the cases is set at a point of $V_{in} = V_1$ with respect to the input voltage V_{in} (V_1 indicates the lowest operating voltage of a regulator load L).

In the voltage regulator of the present invention constructed in this way, when the input voltage V_{in} is 30 higher than the lowest operating voltage V_1 , the load L is controlled by the output voltage V_{out} which is higher than the lowest operating voltage V_1 but lower than the input voltage V_{in} , and hence, the power dissipation is reduced while maintaining suitable operation. When the input voltage V_{in} is low, the load L is controlled by the output voltage which is substantially equal to the input voltage V_{in} or somewhat smaller than it, and hence, a voltage near the lowest operating voltage V_1 of the load L for the input voltage V_{in} is supplied. Since the output voltage V_{out} is reduced to a voltage suited to the load L for the high input voltage V_{in} , this voltage regulator can provide the load L with a low power dissipation and a wide range of input voltages V_{in} .

This feature of the present invention will be described in detail with reference to the graph of Figure 35(b) by comparison with the prior-art voltage comparing regulator having no offset.

40 In the Figure, the axis of the abscissa represents the input voltage V_{in} , while the axis of the ordinate represents the output V_{out} and the reference voltage V_{ref} . Straight line a_1 indicates V_{out} , equal to V_{in} , hence, a virtual curve in the case where the load L is operated directly by the input voltage V_{in} without employing the voltage generator.

Curve c indicates a reference voltage V_{ref1} generated from any of the reference voltage generating devices 45 in various forms. Depending on the form of the device, the reference voltage generating circuit device RVG uses parameters of semiconductor devices such as the threshold voltage V_{th} of a MOSFET, the mutual conductance g_m , the forward voltage V_F or backward Zener voltage V_Z of a PN-junction, and the current gain h_{fe} of a bipolar transistor. Therefore, the reference voltage V_{ref1} depends upon the supply voltage V_{in} according to the voltage dependence of the parameter $[V_{ref1} = f(V_{in})]$.

50 In the case where such a reference voltage V_{ref1} is used as the reference voltage of the voltage comparator circuit VC and where the comparator circuit VC is not provided with the offset as previously stated, the output voltage V_{out} becomes equal to the reference voltage V_{ref1} and agrees with the curve c . Since the reference voltage V_{ref1} does not become higher than the input voltage V_{in} , the output voltage V_{out} becomes lower than the input voltage V_{in} in any range. As a result, the input voltage V_{in} at the time when the output 55 voltage V_{out} becomes equal to the lowest operating voltage V_1 of the load (point R) becomes V_2 ($V_2 > V_1$). Hence, the usable range of input voltages V_{in} as viewed from the load L suffers a loss of a voltage component corresponding to $|V_2 - V_1|$.

In order to make this loss small, in the voltage regulator of Figure 35(a) according to the present invention the operational amplifier VC making up the voltage comparator balances when the inverting input (-) has 60 become higher than the non-inverting input (+) by the offset voltage ΔV_{off} .

Due to the offset voltage ΔV_{off} of the operational amplifier VC, a reference voltage V_{ref2} (curve d) which is smaller than the virtual reference voltage V_{ref1} and which has a similar characteristic is employed as an actual reference voltage V_{ref} . The values of V_{ref2} and ΔV_{off} are set so that a substantial comparison voltage $(V_{ref2} + \Delta V_{off})$ at an input voltage V_3 in the normal operation may become equal to the virtual reference 65 voltage V_{ref1} , so that it may agree with a desired operation point S.

With such a construction, the voltage comparator VC formed into the voltage follower balances under the condition of $V_{out} = V_{ref2} + \Delta V_{off}$. Since input voltages V_{in} satisfying the balance condition are only $V_{in} \geq V_{ref2} + \Delta V_{off}$.

In case where the input voltage V_{in} is smaller than $(V_{ref2} + \Delta V_{off})$, the output voltage V_{out} also becomes 5 smaller than it, so that the voltage comparator VC functions to raise the output voltage V_{out} . This feedback control, however, is limited when the output voltage V_{out} has become equal to the input voltage V_{in} .

Accordingly, with the inflection point P at $V_{in} = V_{ref2} + \Delta V_{off}$, the output voltage V_{out} is reduced (limited) to $V_{ref2} + \Delta V_{off}$ (curve b₁) when the input voltage V_{in} is higher than the inflection point P, and it is made substantially equal to the input voltage V_{in} (curve a₂) when V_{in} is lower than the inflection point.

10 If the inflection point P is the same as or higher than the lowest operating voltage V_1 (point Q) with respect to the input voltage V_{in} (on the axis of abscissas), the foregoing loss can be avoided.

This is because the curve b₁ has a point of intersection with the straight line a₁ due to ΔV_{off} . In the case where the operational amplifier does not have the offset voltage ΔV_{off} and where there is no point of intersection with the straight line a₁ as in the curve d, such an effect is not achieved.

15 Although a MOS FET T_C in Figure 35(a) functions as a source follower, it is a depletion mode N-channel FET, so that it makes $V_{out} = V_{in}$ possible when $V_{in} \leq V_{ref2} + \Delta V_{off}$ and that its threshold voltage V_{th} has no loss. Hence, this applies when the input voltage V_{in} is small.

This, however, does not prevent the use of a source follower FET of the enhancement type. The enhancement type FET is effective in the case where the input voltage is large, the V_{th} loss is not a serious 20 problem and where the adoption of a depletion mode FET manufacturing process is difficult. In this case, curve a₂ ($V_{out} = v_{in}$) which determines lower output voltages V_{out} (below the changing point P) merely shifts downwards by V_{th} ($V_{out} = V_{in} - V_{th}$), and it is similarly possible to produce the effect on the output voltage V_{out} as previously stated.

In the Figure, the N-channel FET can be replaced with a P-channel FET. In this case, the P-channel FET 25 functions with the source earthed, and the loss of V_{th} above described is not involved.

Whether the source earthing or the source follower is adopted as the controlling FET does not produce any essential differences. However, in the case of the source earthing, any special accounting for the loss of the threshold voltage V_{th} as in the case of a depletion mode FET is not necessary. In the case of the source follower, when the operation of the voltage comparison needs to be cyclically sampled (for example, when 30 the comparator is subjected to the clock drive in order to render the power dissipation low), this FET is convenient as it functions as a voltage follower. This is because the output voltage is determined by the gate voltage if the mutual conductance g_m of the FET is sufficiently high.

It is also possible to use a bipolar transistor as the controlling transistor.

It is possible that the offset ΔV_{off} becomes a function of the input voltage V_{in} . In setting the inflection point 35 P, however, it is desirable that ΔV_{off} is constant with respect to V_{in} .

If a reference voltage which has a fluctuating factor similar to that of the load L is used as the reference voltage V_{ref2} , output voltages V_{out} corresponding to the characteristic of the load L can be obtained. If, in that case, V_{ref2} is set in advance to the lowest voltage at which the load L can operate ΔV_{off} can be used as means of a safety margin.

40 While a construction for providing the offset ΔV_{off} , and an application circuit use the difference of the threshold voltages of two MOS FETs according to the principle of the present invention, to be described later, another method for providing the output voltage V_{out} with an inflection point will be explained herewith reference to the circuit diagram of Figure 36(a) and the graph of Figure 36(b).

In the following description and the graph of Figure 36(b), all the voltage values shall be absolute values.

45 In Figure 36(a) is shown a controlling transistor Q₁₀₇ which is made of an N-channel depletion mode FET. N-channel FETs Q₁₀₁ and Q₁₀₂, and P-channel FETs Q₁₀₄ and Q₁₀₅ construct current mirror circuits. A drain current approximately equal to the drain current of Q₁₀₃ flows through a diode-connected P-channel FET Q₁₀₄ and a diode-connected N-channel FET Q₁₀₅. The source-drain voltage drops V_{DS} of the diode-connected P-channel FET Q₁₀₄ and N-channel FET Q₁₀₅ become approximately equal to respective threshold voltages 50 V_{thp} and V_{thn} due to the high impedance loads Q₁₀₂ and Q₁₀₆. Hence, voltages V_{thp} and $(V_{out} - V_{thn})$ are applied to the non-inverting input (+) and the inverting input (-) of an operational amplifier VC constructing a voltage comparator (curves d and b in Figure 36(b)).

If the operational amplifier VC has no offset, it balances when both the inputs of the non-inverting input (+) and the inverting input (-) are equal. Hence, the equilibrium condition is $(V_{out} - V_{thn}) = V_{thp}$, or $V_{out} = V_{thp} + 55 V_{thn}$. The output voltage V_{out} is limited to $(V_{thp} + V_{thn})$ where $V_{in} \geq V_{thn}$, and it becomes substantially equal to V_{in} when $V_{in} \leq V_{thp} + V_{thn}$. Thus in the case where the load L is constructed of a complementary MOS integrated circuit (CMOSIC), the operating lower-limit voltage of the CMOS circuit usually becomes $(V_{thp} + V_{thn})$ and the output voltage V_{out} can compensate for it.

Although the threshold voltage to be derived by the diode-connected MOS Q₁₀₄ and Q₁₀₅ is close to the inherent threshold voltage, it is not equal to it and follows up the drain current of the circuit. It is favourable to make the output voltage V_{out} of the equilibrium point somewhat greater than the inherent value $(V_{thp} + V_{thn})$. To achieve this, the mutual conductance of the FET Q₁₀₃ may be made small so that the current to flow through each MOS diode Q₁₀₄ or Q₁₀₅ is small.

The approximate threshold voltage to be derived by the MOS diode requires the flow of the drain current. 60 Therefore, the circuit must be constructed so that the currents may flow through both the diodes even when

the input voltage V_{in} becomes low.

The reference voltage generating device constructed according to the present invention can generate the difference voltage of the threshold voltages of MOS as the reference voltage, and can therefore be constructed as MISFETs. Hence, it can be used extensively as various constant-voltage sources in monolithic

5 integrated circuits for an electronic desk top calculator, an electronic timepiece etc. made up of MISFETs. As illustrated by way of example, in Figure 37, a lifetime detector circuit for a battery can be obtained by applying the output of the reference voltage generating device (N^+ -gate N-channel MOS Q_1 , P^+ -gate, N-channel MOS Q_2 , resistor R_1) as shown in the foregoing embodiment to one input of a voltage comparator circuit 7 as a reference voltage and a voltage obtained by dividing a battery voltage V_{DD} by means of divider

10 resistors R_{10} , R_{11} is applied to the other input.

In this case, since the battery voltage does not lower suddenly, it is desirable to drive the constant-voltage generator circuit, the voltage divider circuit and the voltage comparator circuit with clock pulses, to achieve reduction of current consumption. Similarly, in the case where the constant-voltage output is not required at all times, the constant-voltage generator circuit may be clock driven as stated above.

15 The circuit for obtaining the difference of the threshold voltages of the MISFETs Q_1 , Q_2 is not restricted to the construction of the above embodiment, but it can be modified variously and any suitable circuit arrangement may be used.

Figure 38 shows another embodiment in which this invention is applied to a battery checker.

FETs Q_1 , Q_2 , Q_7 and Q_9 constitute a constant-current circuit. FETs Q_3 , Q_5 , Q_4 , Q_6 and Q_7 constitute a 20 differential circuit. Q_{11} and Q_{10} provide the clock drive to achieve a reduction in the power dissipation.

Resistors R_1 and R_2 constitute a battery voltage divider circuit for setting the detection level of a battery voltage. Logic elements G_1 and G_2 function to latch an output owing to Q_8 and Q_9 .

Q_4 and Q_6 are an N^+ -gate P-channel MOS and a P^+ -gate N-channel MOS, respectively. By ion implantation of equal quantities, Q_6 is operated in the depletion mode.

25 The embodiment shown in Figure 38 is a battery checker for a timepiece. In the case where the detection level is set between 1.3 v and 1.5 V, a current flowing through Q_7 has a positive gradient of temperature variation, and the difference (= band gap voltage = 1.1 V) of the threshold voltages of Q_4 and Q_6 has a negative gradient of temperature variation. Therefore, the dimensional ratio of the MOSFETs is set so that the conductance of Q_6 may become smaller than the conductance of Q_4 .

30 Figure 39 shows a high-precision reference voltage generating circuit of the voltage follower type utilizing an operational amplifier. N-channel MOSFETs of the P^+ -gate and N^+ -gate are used for Q_4 and Q_5 , respectively. Also, the conductances of the FETs are made different to produce an offset voltage. By adjusting a resistor R_1 outside an IC, a constant current flowing through a constant-current source Q_6 is adjusted, to adjust the offset voltage. Thus, the fine adjustment of a reference voltage is made possible.

35 Alternatively, a Schmitt trigger circuit composed of MISFETs as shown in Figure 40(a) which has reduced the number of constituent elements has been proposed by one of the inventors (Japanese Patent Application No. 52-147085 entitled "Schmitt Trigger Circuit" filed December 9, 1977).

The circuit shown in Figure 40(a) is such that two inverters are connected in cascade and that a MISFET (T_3) forming a positive feedback circuit is provided between the input and output of the inverter on the output 40 side. With this circuit, the width of a hysteresis curve (the difference of two logic threshold values V_{TL1} and V_{TL2}) deviates due to variations in the supply voltage (V_{DD}), the threshold voltages (V_{th}) of MISFETs, etc. Therefore, in such a case, where the circuit is applied to an oscillator whose output oscillates within the voltage width, there is the disadvantage that the frequency deviates.

The present invention employs MISFETs formed by a method in which the threshold voltage of one (T_2) of 45 MISFETs constituting the first-stage inverter in Figure 40(a) is made higher than that of the other MISFET having the same conductivity type channel by a voltage component based on the difference of Fermi levels. In this way, it is intended that the width of the hysteresis curve of the Schmitt trigger circuit (the difference of two logic threshold voltages) assumes a fixed voltage (a voltage substantially equal to the Fermi level difference) fluctuating little against the supply voltage, the manufacturing deviations of the MISFETs,

50 temperature changes, etc.

This feature of the present invention will now be described using one embodiment as an example.

Referring to Figure 40(a), the Schmitt trigger circuit is constructed of an inverter 1 to which an input signal V_i is applied, an inverter 2 which receives an output of the inverter 1 as its input and which forms an output signal V_o , and a MISFET T_3 which is situated between an input terminal and a ground terminal of the inverter

55 2 and which is controlled by the output signal V_o .

The MISFET T_3 acts as positive feedback means of the output side inverter 2. The operation of positively feeding the input signal of the inverter 2 to the output signal is inseparable from the operation of the inverter 1 forming the input signal. The circuit operation is more easily understood when explained in terms of the input side inverter 1.

60 When the input signal V_i is at a high level (earth potential) the output of the input side inverter 1 is at a low level ($-V_{DD}$) because the N-channel MISFET T_1 is "on" and the P-channel MISFET T_2 is "off". The N-channel MISFET T_4 of the output side inverter 2 receives this output of the input side inverter 1 and turns "off" and the P-channel MISFET T_5 turns "on", so that the output of the output side inverter 2 is at the high level (earth potential). For this reason, the P-channel MISFET T_3 drops into the "off" state.

65 When, in this condition, the input signal V_i is going to change to the low level, the output of the inverter 1

5

10

15

20

25

30

35

40

45

50

55

60

65

forms an output signal which is dependent upon the level of the input signal V_i and which is determined by the impedance ratio of the MISFETs T_1 , T_2 , because the MISFET T_3 is "off". The input level of the output side inverter 2 is changed from the low level to the high level.

Hence, when the output of the output side inverter 2 is changed from the high level to the low level and this 5 output signal V_o has exceeded the threshold voltage of the MISFET T_3 , the MISFET T_3 starts the "on" operation. Due to the "on" operation of the MISFET T_3 , the output level of the input side inverter 1 is determined by the impedance ratio between the MISFET T_1 and the parallel MISFETs T_2 , T_3 , and it is shifted onto a higher level state. Thus the "on" operation of the MISFET T_3 , which is controlled by the output of the 10 output side inverter 2, causes positive feedback, in which the input level of the output side inverter 2 is changed into the high level state, is applied to the input of the output side inverter 2. Then, the output signal 15 V_o changes abruptly. Hence, the logic threshold value V_{TL2} in Figure 40(b) is determined by the threshold voltage V_{th1} and V_{th2} and mutual conductances β_1 and β_2 of the MISFETs T_1 , T_2 in Figure 40(a). That is,

$$V_{TH2} = \frac{V_{DD} - V_{th1} + \sqrt{\frac{\beta_2}{\beta_1}} V_{th2}}{1 + \sqrt{\frac{\beta_2}{\beta_1}}} \quad \dots \quad (51)$$

Alternatively, when the input signal V_i is at a low level, the N-channel MISFET T_1 of the input side inverter 1 is "off" and the P-channel MISFET T_2 is "on", the H-channel MISFET T_4 of the output side inverter 2 is "on" 25 and the P-channel MISFET T_5 is "off", and the P-channel MISFET T_3 is "on" due to the low level of the output signal V_o , so that the output signal of the input side inverter 1 is determined by the impedance ratio between the MISFET T_1 and the parallel MISFETs T_2 , T_3 . 25

Hence, in the period in which the input signal V_i changes from the low level to the high level, unless the 30 input signal V_i becomes higher than the logic threshold voltage V_{TL2} in the preceding operation, the output signal of the input side inverter 1 does not change to the low level. However, once this output (the input signal for the output side inverter 2) has begun to change towards the low level and to change the output of the output side inverter 2 into the high level state, the impedance of the MISFET T_3 changes to increase. Therefore, the positive feedback in which the change of the output of the input side inverter 1, i.e. the input signal of the output side inverter 2 is promoted is applied, and the output signal V_o changes abruptly. Hence, 35 when the P-channel MISFET T_2 has its gate electrode formed of a semiconductor of the opposite conductivity type (N-type) to the conductivity type (P-type) of the gate of the conventional P-channel MISFET T_3 or formed of an intrinsic (i-type) semiconductor, it has a threshold voltage which is higher than the threshold voltage V_{TH} of the ordinary MISFET T_3 by a voltage corresponding to the difference of Fermi levels e.g. to the difference of the intrinsic level and the Fermi level, respectively. 35

40 Hence, the logic threshold voltage (V_{TL1}) in Figure 40(b) is approximately expressed as follows: 40

$$V_{TL1} = \frac{V_{DD} - V_{th1} + \sqrt{\frac{\beta_3}{\beta_1}} V_{th3}}{1 + \sqrt{\frac{\beta_3}{\beta_1}}} \quad \dots \quad (52)$$

$\beta_2 = \beta_3$ is held by making the sizes of the MISFET T_1 and the MISFET T_2 equal. Therefore, the difference ($V_{TL2} - V_{TL1}$) of the two logic threshold values becomes:

$$V_{TL2} - V_{TL1} = \frac{\sqrt{\frac{\beta_2}{\beta_1}}}{1 + \sqrt{\frac{\beta_2}{\beta_1}}} (V_{th2} - V_{th3}) \quad \dots \quad (53)$$

Hence, the difference ($V_{TL2} - V_{TL1}$) of the logic threshold values in Figure 40(b) assumes a fixed voltage 65 which is proportional to the difference ($V_{th2} - V_{th3}$) of the threshold voltages of the MISFET 2 and the MISFET 65

3, i.e. the difference of the Fermi levels of the gate electrodes of these MISFETs 2 and 3.

One example of obtaining the voltage corresponding to the difference of the Fermi levels is to utilize the difference of the threshold voltages V_{th} of two MOSFETs having semiconductor gate electrodes which have different conductivity types and which are formed on gate insulating films formed on an identical

5 semiconductor substrate by an identical process.

Figure 59 previously referred to represents conceptually the sectional structure of the respective FETs, and the structure can be fabricated by the MOS manufacturing process illustrated in Figures 73(a) - 73(f).

Subsequently for the sake of brevity, the MOS transistor whose gate electrode is made of a P⁺-type semiconductor shall be called the "P⁺ gate MOS", and the MOS transistor whose gate electrode is made of

10 an N⁺-type semiconductor shall be called the "N⁺ gate MOS".

The difference ($V_{thP^+} - V_{thN^+}$) of the threshold voltages of the P⁺ gate MOS and the N⁺ gate MOS is the difference of the Fermi potentials of semiconductors making the gate electrodes as seen from Equation (16).

While the above description has been made by taking the P⁺-channel MOS transistor as an example, the same applies in the case of an N⁺-channel MOS transistor. Also, the same applies to the i-type gate MOS

15 whose gate electrode is made of an intrinsic semiconductor.

Figure 41 shows a Schmitt trigger circuit according to another embodiment of the present invention. The difference between this and the embodiment of Figure 40(a) is that an input inverter 11 includes a P⁺-gate P-channel depletion type MOS transistor T₁₁ as a load, a P⁺-gate P-channel enhancement type MOS

transistor T₁₂ as drive and an N⁺-gate P-channel enhancement type MOS transistor T₁₃ for feedback, and that

20 an output inverter 12 includes a P⁺-gate P-channel depletion type MOS transistor T₁₄ as a load and a P⁺-gate P-channel enhancement type MOS transistor T₁₅ for drive. The embodiments both ensure that the difference of logic threshold values becomes a constant voltage proportional to the difference of the Fermi levels of the gate electrodes of the MISFET 12 and MISFET 13.

An oscillator will now be described as an example of an application of the Schmitt trigger circuit of the 25 present invention.

Figure 42 is a circuit diagram of an oscillator to which the Schmitt trigger circuit of this invention is applied. A part enclosed within dotted lines in Figure 42 is the Schmitt trigger circuit. An output of the Schmitt trigger circuit STC becomes an input of an inverter 3, an output of which becomes an input of the Schmitt trigger circuit STC.

30 When a supply voltage is closed, the potential of the point d approaches the potential $-V_{DD}$ gradually. When it has exceeded the threshold voltage V_{TL2} of the Schmitt trigger circuit STC, the potential of the point f changes to the earth potential, and the potential of a point g changes to the supply voltages $-V_{DD}$. Then, as the point g is the input of the inverter 3, a MISFET T₄ turns "on", and the potential of the point d approaches the earth potential immediately. When the potential of the point d is below the logic threshold voltage V_{TL1} of

35 the Schmitt trigger circuit STC, the potential of the point f changes to the earth potential, and the voltage of the point g changes to the supply voltage $-V_{DD}$. Therefore, the MISFET T₄ of the succeeding inverter 3 turns "off", and the potential of the point d is charged according to a time constant CR which is determined by a resistor R and a capacitor C connected to the point d. When the potential of the point d gradually approaches the supply voltage $-V_{DD}$ and has exceeded the threshold voltage V_{TL2} of the Schmitt trigger circuit STC, the

40 potential of the point f changes to the earth potential, and the potential of the point g changes to the supply voltage $-V_{DD}$. Subsequently, the inversions are similarly repeated to cause oscillation. Since the potential of the point d alternates between the two logic threshold voltages V_{TL1} , V_{TL2} of the Schmitt trigger circuit STC, the oscillation frequency of the oscillator is determined by the speed at which charges are stored into or discharged from the capacitor C by the resistor R or the MISFET T₄. Assuming that the resistance R is

45 sufficiently greater than the impedance of the MISFET T₄, the oscillation frequency of the oscillator circuit is determined by only R and C, and the oscillation has a frequency which is stable against fluctuations in the supply voltage, temperature changes, manufacturing deviations, etc.

When the resistor R is mounted outside the integrated circuit, only one terminal suffices for the integrated circuit of the oscillator circuit, and stable oscillation can be achieved under such a condition.

50 The resistor R may be any of, a diffusion resistor, a resistor owing to a MISFET, etc. However, when a resistor of sufficiently small variation is formed in an integration circuit, the oscillator circuit can be entirely contained within such a circuit.

Figure 43 is a circuit diagram showing an example of an oscillator circuit using the Schmitt trigger circuit STC as shown in Figure 41 in which the width of hysteresis is constant according to the present invention. A 55 third inverter 3 is connected to the input of the Schmitt trigger circuit STC, a fourth inverter 4 is connected to the output of the Schmitt trigger circuit STC, and a resistor R and a coupling capacitor C for determining the oscillation frequency are connected to the input of the third inverter 3.

The threshold voltage V_{th} of MOSFETs which are discrete elements in a MOS integrated circuit form an important parameter which determines the characteristics of a Large Scale Integration device (herein referred to as LSI). The threshold voltage V_{th} shows large variations due to the manufacturing process and exhibits a large variation due to temperature changes, and the control of V_{th} is difficult in the manufacture of a Metal Oxide Semiconductor Large Scale Integrator (herein referred to as a MOSLSI).

According to the present invention, as shown by way of example in Figure 50, a bias voltage V_{BB} is applied to the silicon substrate of a MOS memory IC to reduce parasitic capacitances. In order to obtain the bias 65 voltage V_{BB} , a substrate bias generating circuit SBGC is employed. The substrate bias generating circuit

SBGC has an arrangement which is illustrated in Figure 47.

In the present invention, the comparator employing the difference of the work functions of the gate electrodes of MIS FETs as previously discussed is used in the substrate bias generating circuit SBGC to control V_{th} so that it is a constant voltage.

5 V_{th} changes in dependence on the substrate bias V_{BB} , and is expressed by the following equation:

$$V_{th} = V_{th0} + K (2\phi_F + |V_{BB}| - 2\phi_F)$$

10 where V_{th0} denotes V_{th} when the substrate bias voltage V_{BB} is zero, K denotes the substrate effect constant, and ϕ_F denotes the Fermi level. Therefore, V_{th} may be controlled by varying the substrate bias V_{BB} . The 10
substrate bias voltage generating circuit SBGC shown in Figure 47, has a V_{th} sensing circuit 471, a
comparator 472, an oscillator circuit 473 and a waveform shaping circuit 474. The oscillator circuit 473 may
be replaced with a different oscillator circuit. The waveform shaping circuit 474 is composed of two MOS
15 diodes Q_1 and Q_2 and a capacitor C_1 , and it functions to drawing out charges of V_{BB} to the earth point by a
pumping action. Owing to the pumping action, V_{BB} is drawn towards a negative voltage. The maximum
voltage V_{BBM} of $|V_{BB}|$ is determined by the point at which the drawing-out voltage owing to the pumping
action and the substrate leakage current are stabilized. Provided the oscillation circuit is operating, V_{BB} is
held at the stable point V_{BBM} . After the oscillation ceases, however, the charges of the substrate leak due to
20 the substrate leakage current and V_{BB} approaches the earth potential. When V_{BB} has become close to the
earth potential, V_{th} lowers.

The comparator circuit 472 shown in Figure 47, exploits the difference of the Fermi levels of the gate
electrodes, and an example in the N-channel process is shown in Figure 21. The comparator circuit 472
employs an intrinsic silicon gate MOS as Q_1 in Figure 21, and an N gate MOS as Q_2 . These are depletion type
25 MOS. Therefore, this comparator inverts when a voltage of $Eg/2 = 0.55$ V has been put into an inverting input
(-). The V_{th} sensing circuit 471 in Figure 47 is composed of a resistance and a diode-connected MOSFET Q_3 .
The resistance may be either a polycrystalline silicon diffused layer resistance or a MOS resistance, and the
resistance value is set so that an output may become 0.55 V when V_{th} of Q_3 has become 0.55 V. When the
substrate bias voltage V_{BB} is close to the earth potential and V_{th} of Q_3 is below 0.55 V, the (-) input voltage of
30 the comparator circuit falls below 0.55 V, the output of the comparator becomes "1" and the oscillation
circuit continues to operate. When the substrate bias voltage V_{BB} approaches V_{BBM} and V_{th} rises and exceeds
0.55 V, the comparator output becomes "0", the oscillation ceases and the substrate bias voltage V_{BB}
becomes close to earth potential due to the leakage. Hence, since a feedback loop is formed, V_{th} is controlled
at the stable point by this substrate bias generator circuit SBGC. The voltage 0.55 V obtained in the
35 comparator portion 472 is 1/2 of the energy gap, which fluctuates little with temperature changes,
manufacturing dispersions and supply voltage fluctuations. Therefore, it becomes possible to control V_{th}
with a very high precision, and a MOSLSI with a wide temperature margin, manufacturing process margin
and power supply margin is obtained. As will be discussed later, the intrinsic silicon gate MOS Q_1 of the
comparator portion 472 can be obtained by an identical process to that for obtaining a high resistance load R
40 in a memory cell shown in Figure 51, so that the control of V_{th} can be readily achieved with the prior-art
process.

In an embodiment where a 5 V power supply is employed as a power source in a MOSLSI and where
signals from a TTL logic circuit are employed as inputs, the outputs of the TTL logic circuit become 2.0 V as a
high level and 0.8 V as a low level. In converting the TTL signals into the MOS levels, it has previously been
45 necessary to take the ratios of inverters in an input portion and to convert them into the MOS levels. However,
there is the problem that the input level margin becomes small due to the variation of V_{th} and temperature
changes.

Figure 45 shows a TTL → MOS signal level converter circuit which employs the reference voltage V_{ref}
generated from the reference voltage generating circuit utilizing the difference of the Fermi levels of the gate
50 electrodes as previously described. The signal level converter circuit in Figure 45 is preferably applied to the
address buffer circuits XAB and YAB of the MOS memory shown in Figure 50. As the reference voltage V_{ref} , a
reference voltage of 1.4 V is generated by the previously discussed reference voltage generating circuit of
Figure 15. A differential amplifier employing MOSFETs in Figure 44 is employed as an amplifier, AMP in
Figure 45, and an input buffer in which the logic threshold voltage of an input is 1.4 V equal to the reference
55 voltage V_{ref} is prepared. With this method, a TTL → MOS signal level converter circuit may be obtained.

Alternatively, a signal level converter circuit which has the logic threshold voltage of 1.4 V can be obtained
by employing the circuit shown in Figure 13 as the amplifier, AMP in Figure 45. The inphase input (+) ② is
earthing as shown in Figure 14, and an address signal $A_0 - A_4$ is applied to the antiphase input (-). Depletion
type MOS FETs are used for the transistors T_1 and T_2 . By making the threshold voltages V_{th1} and V_{th2} of the
60 respective FETs unequal, the operational amplifier is provided with an input offset voltage of 1.4 V.

The circuit in Figure 46 is intended to hold the logic threshold voltages of logical circuits, such as an
inverter, constant against changes in the serve supply voltage, the threshold voltages of MOS transistors,
temperature changes, etc.

An inverter 1 composed of FETs Q_2 and Q_3 and an inverter 2 composed of Q_5 and Q_6 are provided with
65 MOS FETs Q_1 and Q_4 respectively for controlling the logic thresholds.

A logic threshold detector circuit 3 which is composed of a controlling MOSFET Q₇ and an inverter Q₈, Q₉ with its input and output coupled is constructed to be similar to the inverters 1 and 2 described above (the pattern size ratios of MOSFETs are equal). Due to the coupling of the input and output of the inverter Q₈, Q₉, the logic threshold voltage is obtained.

5 CMP1 indicates the comparators circuit previously discussed with reference to Figures 13 and 14 which has the reference voltage V_{ref} as the offset of the differential circuit. The comparator circuit CMP1 compares the logic threshold and the reference voltage and controls the gate voltage of the controlling MOSFET Q₇ so that the difference of both the voltages may become substantially zero.

Thus, if the logic threshold is greater than the reference voltage V_{ref}, the output of CMP1 is at a high level, 10 and the equivalent resistance of Q₇ increases and this transistor functions to lower the logic threshold. In case where the logic threshold is less than the reference voltage V_{ref}, the converse is true. Both the voltages fall into the equilibrium state when they are equal.

The gate voltages of the controlling MOSFETs Q₁ and Q₄ are connected to the gate voltage of the controlling MOSFET Q₇, and the former transistors and the latter transistors have a similar relationship.

15 Thus, the logic thresholds of the inverters 1 and 2 become equal to the reference voltage, and very stable inverter characteristics are exhibited.

This is not restricted only to inverters, but is similarly applicable to the other logical circuits such as NAND and NOR.

It is readily applicable to the case of inverters and the like logical circuits of ordinary single-channel types, 20 not the CMOS construction.

These circuits are useful as input interface circuits which can digitally process signals reliably especially when the ranges of input levels and logic amplitudes are narrow.

Examples in which the reference voltage generator means according to the present invention is applied to a status setting circuit (an auto-clear circuit) for electronic devices will now be discussed.

25 Figure 48 is a circuit diagram showing an example of a status setting circuit, which is a flip-flop circuit constructed of two inverters each including two MOSFETs. Referring to the Figure, in case where potentials at points a and b are zero, both the MOSFETs T₁ and T₃ change to the "ON" state when a power supply -V_{DD} is applied because they are N-channel MOSFETs. Simultaneously with the application of the supply voltage, the potential points a and b changes towards the supply voltage -V_{DD}. At this time, the Fermi levels of the 30 gate semiconductors of the N-channel MOSFETs T₁ and T₂ differ from each other, and the threshold voltage V_{th3} of the MOSFET T₃ is about three times greater than that V_{th1} of the MOSFET T₁ (for example: V_{th1} = 0.45 V, V_{th3} = 1.25 V). Therefore, during a drop in the supply voltage, the MOSFET T₃ turns "OFF". Since the MOSFET T₁ continues to be in the "ON" state, the points b and a are respectively stabilized at -V_{DD} and the earth potential.

35 In the case where, with the power supply -V_{DD} disconnected, the potential of the point a is zero and charges remain at about 1 V at the point b, T₃ is in the "OFF" state till V_{DD} equals V_{th3} during the drop in the supply voltage, and the MOSFET T₁ changes to the "ON" state at V_{DD} equals V_{th1}. Therefore, even when the potential of the point a has been zero and the potential of the point b has been about one volt (or up to V_{thN} of T₃) in the initial state, the potential of the point b becomes V_{DD} and the potential of the point a becomes zero 40 in the stable state. Also, since all the FETs are constructed of E(enhancement)-MOSFETs in the present circuit, the current consumption in the stable state is almost zero.

Figure 49 is a circuit diagram which shows an embodiment of a status setting circuit which has been proposed in the prior art. Referring to the Figure, the threshold voltage V_{th} of MOSFETs T₂ and T₄ are equal to each other, and an N-channel D (depletion)-MOSFET T₁ is inserted to increase the stability of a latch circuit.

45 Due to the D-MOSFET, when the power supply -V_{DD} is applied, the potential of the point a falls simultaneously with the power supply without exception, and the point b does not turn "ON" unless the supply voltage falls to V_{th} of the MOSFET T₄, so that the potential of the point a and the potential of the point b become -V_{DD} and zero respectively in the stable state. Since, however, the D-MOSFET is inserted between the point a and -V_{DD} in the present circuit, the P-MOSFET T₃ turns "ON" when the state in which the 50 potential of the point b is -V_{DD} and the potential of the point a is zero (RESET) is subsequently established and a D.C. path due to T₁ and T₃ arises to cause a high current consumption. In contrast, with the status setting circuit of the present invention as shown in Figure 48, the status setting can be achieved reliably and the current consumption is very low as described above, and hence, effective status setting means can be provided.

55 An embodiment in which the present invention is applied to a semiconductor random access memory (RAM) will now be described.

In general, in a storage device constructed of a static RAM, voltage control to lower a supply voltage is performed in order to reduce power dissipation at the time when the storage device is not used (stand-by status). This is called the data retention mode.

60 In this case, a signal voltage is lowered simultaneously with the supply voltage. Since a power supply line has a greater time constant than a signal line, the signal voltage lowers to a predetermined value more rapidly. Usually, in a semiconductor RAM, a store control signal is set at a supply voltage level, a recall control signal at a reference voltage level, and a chip select signal at a reference potential level.

In the data retention mode, therefore, the level of the control signal lowers faster than the supply voltage, 65 so that the store control signal becomes the recall control signal level instantaneously and that the chip

select signal is formed. For this reason, the recall operation is effected instantaneously, and the information of a bit selected at that time is destroyed.

In order to solve this problem, in a RAM constructed of field-effect transistors of a single channel, it is possible to provide a time constant circuit to make the time constant of the signal line greater. With this measure, however, an external circuit is required, and the control signals are adversely affected.

5

In a C-MOS (complementary MOS) integrated circuit, a p-n-p-n element is frequently formed due to its structure. Therefore, when the signal voltage is made greater than the supply voltage, such a p-n-p-n element operates, and a large current flows between the supply voltage and the reference potential. For this reason, a time constant circuit in which the signal voltage and the supply voltage are lowered at the same time must be used for the C-MOS memory.

10

These facts are serious problems in the design and manufacture of storage devices when considering the use of memory chips.

It is therefore desirable that a circuit for sensing the lowering of the supply voltage is contained in the same chip as that of the RAM. However, MOSFETs on the semiconductor chip have temperature dependence of threshold voltage V_{th} , manufacturing variations, etc., and it has been difficult to obtain a detection voltage necessary for sensing with high precision.

15

This aspect of the present invention will be described below.

Figure 52 is a block diagram of a static type semiconductor memory integrated circuit device showing an embodiment of the present invention.

20 In the Figure, there is shown a memory matrix (64 × 64 bits) circuit 1 which is constructed of static memory cells. An X-decoder circuit 2 discerns an information pattern assigned by a row select signal ($A_0 - A_4$) and applied through a buffer circuit BX, to assign a row (X) line of 1/64. A Y-decoder and input/output circuit 3 discerns an information pattern assigned by a column select signal ($A_5 - A_9$) and applied through a buffer circuit BY, to assign a column (Y) line of 1/64. It also gives the assigned column line of the memory matrix 1
25 an input data applied through gates WB. It also provides an output data from the assigned column line to terminals (1/0₁ - 1/0₄) through gates RB. An input data control circuit 4 gives the input/output circuit the input data to-be-recalled. Also shown are input/output terminals (1/0₁ to 1/0₄) and a chip select signal CS, which indicates the selection of this chip by the "0" level i.e. reference potential level. A store/recall control signal WE controls the recall operation when it is at the "0" level i.e. the reference potential level, and the store
30 operation when it is at the "1" level i.e. supply voltage level. Gate circuits 5, 6 are alternately controlled by the control signals. Thus only when the CS is "0", are the gate circuits controlled by either "0" or "1" of WE,
35 to execute the store or recall operation.

30

A voltage detector circuit 7 detects the data retention mode when the supply voltage has fallen below a predetermined voltage, and it controls the gate circuit 5 to inhibit the signal WE at that time. Thus, the
35 malfunction as previously described is prevented. An example of the arrangement of the voltage detector circuit 7 is shown in Figure 53(a).

35

Resistors R₁, R₂ connected in series form a circuit for dividing a supply voltage V_{cc}. The voltage divider circuit applies a divided voltage a to the gate of an N-channel MISFET Q₂. The supply voltage V_{cc} is applied to the gate of an N-channel MISFET Q₄.

40

40 A MISFET Q₅ has its gate supplied with a suitable bias voltage from d, and constructs a constant-current source. It forms an operational amplifier, together with load MISFETs Q₁ and Q₃ and the two differential input MISFETs Q₂ and Q₄.

The differential input MISFETs Q₁ and Q₄ are formed on, for example, N-type silicon layers of equal conductivities, and the respective gate electrodes are made of different materials so that the threshold voltages may become unequal. The gate electrodes of the two MISFETs Q₂ and Q₄ are made of, for example, silicon, and their conductivity types are made different. The MISFET Q₂ has an N-type silicon gate, whereas the MISFET Q₄ has a P-type silicon gate. As a result, the threshold voltage V_{th4} of the MISFET Q₄ becomes greater than the threshold voltage V_{th2} of the MISFET Q₂ by the difference between the Fermi levels of the P-type and N-type silicon gates.

45

50 Hence, the operation amplifier has an offset voltage equal to the difference of the threshold voltages. If the supply voltage V_{cc} is comparatively large in the circuit of Figure 53(a), the MISFET Q₄ is in the "on" state and Q₂ is in the "off" state, and the potential of a point c is at a low level. Due to lowering of the supply voltage V_{cc}, the potential of the point a changes as indicated by a curve a in Figure 53(b). When, due to the lowering of the supply voltage V_{cc}, the potential difference between the supply voltage V_{cc} and the potential
55 of the point a has become smaller than the offset voltage, the MISFET Q₄ changes to the "off" state and Q₂ changes to the "on" state. In consequence, the potentials of the points b and c in the circuit of Figure 53(a) change as indicated by curves b and c respectively in Figure 53(b). Thus, the potential of the point c is at a high level when the supply voltage V_{cc} has lowered to a predetermined value.

55

As described above, the detection level of the circuit of Figure 53(a) is determined by the offset voltage created by the MISFETs Q₂ and Q₄ and the divided voltage created by the resistors R₁ and R₂. It is not affected by the threshold voltages of the respective MISFETs.

60

The offset voltage is known with a comparatively high precision because it is determined by the difference between the Fermi levels of the gate electrodes of the two MISFETs Q₂ and Q₄ as discussed previously. Since, in a semiconductor integrated circuit, the relative values of the resistances of resistor elements are
65 known with a comparatively high precision, the voltage division ratio created by the resistors R₁ and R₂ is

65

known with a comparatively high precision.

As a result, the detection level of the circuit of Figure 53(a) can be set comparatively accurately.

In Figure 53(b), a waveform d' indicates the output of the gate circuit 5 during the data retention mode during which the gate circuit 5 is not controlled by the detection output.

5 In the data retention mode, the input control signals CS and WE lower faster than the supply voltage V_{cc} of the gate circuit 5. Therefore, when the difference of both the voltages has become above the logic threshold, the output waveform d' is generated as stated above. This is the cause of the malfunction explained previously. 5

10 According to the circuit of the present embodiment, however, the control signal c is applied to the input of the gate circuit 5, so that the waveform d' is inhibited from being provided. Thus, erroneous recall in the data 10 retention mode can be prevented, and data stored in the matrix memory are not destroyed.

15 In accordance with the embodiment described above, erroneous recall in the data retention mode can be prevented. Moreover, the detector circuit can be constructed with a simple circuit arrangement and can be contained in the memory chip. It is therefore unnecessary to care for the prevention of malfunctions on the side of the user of the semiconductor memory device. 15

For example, the gate circuit which is controlled by the voltage detection output may obtain the chip select signal. All the memory cell select signals may be inhibited so as to select no memory cell.

This is because erroneous recall can be prevented when one of conditions necessary for the execution of the recall operation is inhibited.

20 The voltage divider circuit which constitutes the voltage detector circuit in the previous embodiment may utilize resistance by means of MISFETs instead of the resistor elements. Preferably, the resistance of this voltage divider circuit is made large to make the power dissipation low. 20

The two MISFETs of the foregoing embodiment which have silicon gate electrodes of conductivity types opposite to each other are fabricated within a silicon monolithic semiconductor integrated circuit chip. Since 25 these FETs are manufactured under substantially the same conditions except the conductivity types of the gate electrodes, the difference of the threshold voltages V_{th} of both the FETs becomes approximately equal to the difference between the Fermi levels of P-type silicon and N-type silicon. The P-type and N-type gate electrodes are doped with respective impurities to the vicinities of the saturation densities, and the difference becomes approximately equal to the energy gap E_g of silicon (about 1.1 V), which is used as a 30 reference voltage source. 30

The reference voltage generating device based on such a construction has a low temperature dependence and the manufacturing deviations are small.

The voltage detector circuit 7 can be modified in several ways.

35 The reference voltage sources which uses the difference between the Fermi levels of semiconductors forming the gate electrodes of two MOS FETs as shown in Figure 6(b), Figure 8, Figure 9, Figure 10(a), Figure 11(a), Figure 12, Figure 13, Figure 14, Figure 15, Figure 16 and Figure 17 can be used as the reference voltage 35 source for the voltage detector circuit of the present invention.

To achieve this two FETs can be used which have semiconductor gate electrodes of different conductivity types as already explained with reference to Figure 59, for example, a MOS transistor with its gate electrode 40 made of a P⁺-type semiconductor or a P⁺-gate MOS transistor and a MOS transistor with its gate electrode made of an N⁺-type semiconductor or an N⁺-gate MOS transistor. As already described with reference to Figures 73(a) to 73(f), the above two FETs can be manufactured, without the change or addition of any step by the conventional CMOS manufacturing process. 40

If the conventional CMOS manufacturing process is used, the self-alignment structure as shown in Figures 45 65(a) and 65(b) and Figures 66(a) and 66(b) is obtained as discussed below. Since the MOS transistors are of the P-channel type in this case, a P-type impurity is diffused into both end parts of a gate electrode adjoining the source and drain in both the P⁺-gate MOS and the N⁺-gate MOS. In a central part of the gate electrode, a P-type impurity is diffused for the P⁺-gate MOS, and an N-type impurity is diffused for the N⁺-gate MOS. Between the central region and both the end parts adjoining the source and drain, there are regions / in 50 which no impurity is diffused. Thus, the difference of the P⁺-gate MOS and the N⁺-gate MOS is only the conductivity type (P or N) of the semiconductor forming the central region of the gate. 50

Also, in order to reduce the deviation (difference) of the effective channel lengths of the MOS transistors due to the fact that the regions of the gates which are formed for the self-alignment and in which the P-type 55 impurity is diffused, shift onto either the left or right side (source side or drain side) during manufacture due to an error in the mask alignment, the columns of the source regions and the drain regions are alternately arranged, and the left half and the right half are in a linear symmetry with respect to the channel direction as a whole. Hence, even when the misregistration of the mask alignment with respect to the channel direction (leftward or rightward shifting) changes the effective channel lengths of the FETs in the respective columns, the average effective channel lengths of the P⁺-gate MOS and the N⁺-gate MOS in the respective columns 60 connected in parallel have the shifting cancelled out overall and become substantially constant. 60

Besides by making the compositions of the gate electrodes different, unequal threshold voltages are achieved by ion implantation into channels as described with reference to Figure 7, by utilizing a doped gate oxide, by changing the thickness of gate insulating films, etc.

Figure 54 shows an embodiment in which the battery checker of the example of Figure 20 is applied to an 65 electronic timepiece. 65

T_1, T_2, T_{41} to T_{49} and R_{41} and R_{42} form a circuit which checks the voltage level of a mercury battery E_1 having a nominal voltage of 1.5 V. A transistor pair T_1, T_2 in a differential portion is constructed from a P^+ gate N-channel MOS T_1 , and an N^+ gate N-channel MOS T_2 , the channel portions of which are subjected to ion implantation so that the threshold voltages of both the transistors lie within 1.0 V to 1.5 V, being the

5 operating power supply range of the electronic timepiece.

The difference of the threshold voltages to serve as a reference voltage is about 1.1 V in the case of a silicon semiconductor. In order to set a level for detecting that the voltage of the battery E_1 has lowered at about 1.4 V, an adjustment is made by altering the resistance ratio of the resistance means R_{41} and R_{42} .

In order to make the current consumption negligible in practical use, the battery checker is intermittently

10 operated by a clock signal ϕ which is obtained from a frequency divider circuit FD and a timing circuit TM.

An output of the battery checker is held stable by a latch which is composed of NAND gates NA_1 and NA_2 .

The timing circuit TM is controlled by the logic level of an output from the latch circuit, the driving output of a motor is changed and the method of moving a hand of the timepiece is changed so as to indicate the lowering of the battery voltage. The lowering of the battery voltage can also be indicated without changing 15 the movements of the hand, for example, by flickering of an electrooptic device such as a liquid crystal or light emitting diode.

As shown in Figure 54 a crystal oscillator circuit OSC is constructed of a CMOS inverter and also includes components outside the IC, a crystal X_{ta} and capacitors C_G and C_D . A waveform shaping circuit WS converts the oscillation output from a sinusoidal wave into a rectangular wave. Also shown an excitation coil CM of a 20 step motor for driving the second hand and buffers BF_1 and BF_2 which are constructed of CMOS inverters and which serve to drive the excitation coil C_M whilst inverting the polarities every second.

All the circuits within the IC are operated by the mercury battery E_1 of nominal 1.5 V. TM is the timing pulse generator circuit which receives a plurality of frequency division outputs of different frequencies from the frequency divider circuit FD and the control output of the latch composed of NA_1 and NA_2 and which 25 generates pulses having any desired period and pulse width. The IC is a monolithic Si semiconductor chip for a hand-type electronic wrist watch which is constructed by the Si gate CMOS process already explained with reference to Figures 73(a) - 73(f).

Figure 55 shows another embodiment of the construction of a circuit system for an electronic wrist watch containing a battery checker. In this embodiment, the conductances of FETs Q_4 and Q_5 of a differential circuit 30 are made unequal as in Figure 39, and the detection level can be finely adjusted by means of an adjusting resistor R_j outside the IC.

Due to the resistor R_j , variations in manufacture can be avoided in use.

An embodiment in which the voltage regulator as shown in Figure 36(a) is applied to an electronic timepiece will now be explained with reference to Figure 56.

35 In Figure 56, there is shown a crystal oscillator OSC, a waveform shaping circuit WS which converts a sinusoidal wave oscillation output into a rectangular wave, a frequency divider circuit FD, a timing pulse generator circuit TM which prepares pulse of predetermined period and width from frequency division outputs, a level shift circuit LF which converts a signal of low level into a signal of high level, a battery lifetime detector BC, a voltage comparator VC, a voltage regulator VR which uses the voltage comparator VC, a hold circuit H, an oscillation state detector DT, and an excitation coil of a step motor LM for driving a 40 second hand.

40 The detector DT detects that the oscillator OSC has oscillated through the frequency divider FD and the timing circuit TM. If oscillation has occurred the detector DT actuates the voltage regulator VR to lower the operating voltage V_{op} of the oscillator OSC and WS, FD, TM etc. to a value below the battery voltage (-1.5 V).

45 The moment the battery E is turned "on", the input node of an inverter I_1 has earth potential (logic "0") due to a discharging resistor R_{104} , so that an N-channel FET Q_{201} is brought into the "ON" state and the output of the regulator is made -1.5 V, being the battery voltage. At this time, a FET Q_{203} is also turned "ON", and the gate node of a FET Q_{202} is charged. This makes the negative feedback loop of the regulator active to prevent the regulator output dropping the moment the FET Q_{201} is subsequently switched "OFF".

50 When the oscillator has started operating, the other logical circuits are already in the operative state, so that a pulse ϕ_B is supplied from the timing circuit TM to the detector DT. An exclusive OR circuit EX_1 detects the generation of the pulse ϕ_B . One input of the OR circuit EX_1 receives the pulse ϕ_B delayed by inverters I_4 and I_5 and an integration circuit C_{101} and R_{103} . When the pulse ϕ_B is generated, a pulse of a width corresponding to the delay time is generated at the output of the gate EX_1 . This pulse is integrated by a 55 rectifier circuit made up of a FET Q_{225} , an inverter I_6 and a capacitor C_{102} , and turns "OFF" the N-channel FETs Q_{201} and Q_{203} after a short time from the generation of ϕ_B . Thus, the regulator VR generates a predetermined voltage (less than 1.5 V) at the source electrode of the controlling P-channel FET Q_{202} by the negative feedback control loop, and it contributes to reduce the power dissipation of the electronic timepiece.

60 The operation of the regulator, especially the voltage comparator VC, will now be explained. Since this 60 comparator VC effects an operation similar to that of the comparator CP described with reference to the principle diagram of Figure 35(a) and the characteristic diagram of Figure 35(b), only a brief explanation will be given.

Considering the P-channel MOSFETs Q_{206} and Q_{207} , in order to obtain the offset voltage V_{off} , the gate of Q_{206} is P-type as in Q_1 of Figure 60 and Figures 67(a) and 67(b), and the gate of Q_{207} is i-type (intrinsic 65 semiconductor) as in Q_2 of Figure 60 and Figures 68(a) and 68(b). Hence, the threshold voltage V_{th} of Q_{207}

becomes higher than that of Q_{205} by about 0.55 V, which provides offset voltage V_{off} . However, since both an N-channel FET Q_{208} and a P-channel FET Q_{209} are diode-connected, the sum of both the threshold voltages V_{th} , i.e. $(V_{\text{thp}_{209}} + V_{\text{thn}_{208}})$ is applied to the gate of Q_{207} being the non-inverting input (+) of the comparator VC , and the sum serves as the voltage $V_{\text{ref}2}$ as indicated in the curve d in Figure 35(b). Also the gate of the FET Q_{206} being the inverting input (-) of the comparator is connected to the source of the controlling P-channel FET Q_{202} of the source-follower type. 5

Hence, the output voltage V_{out} of the voltage regulator VR which is generated at the source of the controlling FET Q_{202} under the control action of this controlling FET Q_{202} driven by the comparator VC , becomes $V_{\text{out}} = V_{\text{thp}_{209}} + V_{\text{thn}_{208}} + \Delta V_{\text{off}}$ (in case where $V_{\text{in}} = V_{\text{thp}} + V_{\text{thn}} + \Delta V_{\text{off}}$). When the input voltage V_{in} is low, the output voltage becomes $V_{\text{out}} = V_{\text{in}}$ as previously described. Of course, the output voltage V_{out} of the voltage regulator VR is used as the operating voltage V_{op} of the oscillator OSC as well as WS , FD , TM , etc. 10

In order to keep the power dissipation low, this comparator has the operating time limited by a timing signal ϕ_A provided by the on-off operation of the driven FET Q_{211} . This also applies to the circuit for obtaining the reference voltage $V_{\text{ref}2}$. To achieve this, a capacitor C_{104} is connected to the gate of Q_{207} and a capacitor C_{105} is connected to the gate of Q_{202} to store the voltage of the reference voltage $V_{\text{ref}2}$ and to store the gate voltage of Q_{202} respectively. These capacitors C_{104} and C_{105} are added separately from parasitic capacitances such as gate capacitances. A capacitor C_{103} serves to prevent any oscillation created by a phase rotation caused by the cascade connection of several FETs in the feedback loop. 15

Since the battery checker BC has a construction similar to that in Figure 54, the explanation of this device is omitted. 20

At the output stage of the IC, drivers I_2 and I_3 for the excitation coil use the battery of 1.5 V as a power supply to make the driving capability high. 20

Figure 57 shows an embodiment in which the voltage regulator VR and the battery checker BC according to the present invention are applied to a digital display electronic timepiece.

In Figures 57, parts OSC , WS and FD use an adjusted voltage lower than 1.5 V as a power supply similarly to the example of Figure 56, and also logical circuits within an IC such as decoder DC and time correction circuit TC use the lower voltage as a power supply. 25

A voltage doubler circuit DB boosts the voltage of 1.5 V to 3.0 V, which is used as a drive voltage for a liquid crystal display DP (a driver is not shown). Level shift circuits LS_1 , LS_2 convert a low DC signal level into a high one and supply it to circuits of high supply voltages. 30

To render the power dissipation low and to expand the service power supply range it is necessary that the low operating power supply is used for the ordinary logical circuits within the IC which operate at low operating voltages, while the high operating power supply is used for the display driver etc. at an input/output interface of the IC which require high operating voltages. 30

Attention is drawn to Application No. 79.07817 (Publication No. 2,016,801) from which this application has been divided in which there is claimed a reference voltage generating device. 35

Attention is also drawn to the following Divisional Applications:

- DIV. I Application NO. 81. 19559 (Publication No. 2,081,014) in which the claims relate to a method of manufacturing a semiconductor device;
- DIV. II Application No. 81. 19560 (Publication No. 2,081,015) in which the claims relate to a method of manufacturing a semiconductor device; 40
- DIV. IV Application NO. 81. 19562 (Publication No. 2,081,458) in which the claims relate to a battery checker.

45 CLAIMS 45

1. A reference voltage generating device including:
an operational amplifier including first and second insulated gate field-effect transistors (IGFETs) which have a difference of threshold voltages corresponding to a difference of Fermi levels of gate electrodes 50
thereof, both said gate electrodes of said first and second IGFETs being made of an identical semiconductor material but having different conductivity types, a gate of said first IGFET being used as an inverting input of said operational amplifier whilst a gate of said second IGFET is used as a non-inverting input of said operational amplifier, an output terminal for delivering an output signal in response to a potential difference between said inverting and non-inverting inputs, and an input which is offset corresponding to said difference of threshold voltages; 55
a feedback connection means connected between said inverting input and output terminals of said operational amplifier for applying an output signal at said output terminal of the operational amplifier to said inverting input terminal thereof; and
a reference connection means for applying a reference potential to said non-inverting input terminal of the operational amplifier, whereby the reference voltage based on the difference of said threshold voltages of said first and second insulated gate field-effect transistors is derived between said output terminal of said operational amplifier and said reference potential. 60
2. A reference voltage generating device according to Claim 1, wherein said feedback connection means includes a controlling amplifier element having its control electrode coupled to said output terminal of said operational amplifier, its first output electrode, coupled to a power supply terminal, and its second output 65

electrode coupled to said inverting input of said operational amplifier.

3. A reference voltage generating device according to Claim 2, wherein said second output electrode of said controlling amplifier element is coupled to said inverting input of said operational amplifier through a voltage divider means which is connected to said output electrode of said controlling amplifier element. 5

5 4. A reference voltage generating device according to Claim 1, wherein said feedback connection means includes a voltage divider connected between said output terminal of said operational amplifier and said reference potential for applying a divided voltage of the output voltage appearing at said output terminal to said inverting input terminal.

5 5. A reference voltage generating device according to Claim 1 or 2, wherein said second insulated gate field-effect transistor is of the depletion type. 10

6. A reference voltage generating device according to any one of the preceding claims, wherein said operational amplifier includes a third insulated gate field-effect transistor (IGFET) which is commonly coupled in series with drain-source paths of said first and second IGFETs, said third IGFET being driven by a timing signal, whereby during the conductive state of said third IGFET a stabilized output voltage is derived 15 from said output terminal of said operational amplifier. 15

7. A reference voltage generating device according to any one of the preceding Claims 1 to 5, further including:

a first constant current source connected in series with the source-drain path of said first insulated gate field-effect transistor; and

20 20 a second constant current source connected in series with the source-drain path of said second insulated gate field-effect transistor. 20

8. A reference voltage generating device according to any one of Claims 2, 3, 5 and 6, wherein said controlling amplifier element is a fourth insulated gate field-effect transistor (IGFET).

9. A reference voltage generating device according to any one of Claims 2, 3, 5 and 6, wherein said 25 controlling amplifier element is a bipolar transistor. 25

10. A reference voltage generating device constructed substantially as herein described with reference to and as shown in Figures 14, 15, 16, 17, 27, 28, 32, 33, 34, 35a, 39 and 56 of the accompanying drawings. 30

New claims or amendments to claims filed on 26th July, 1982

30 Superseded claims 1 and 8

New or amended claims:-

1. A reference voltage generating device including:
an operational amplifier including first and second insulated gate field-effect transistors (IGFETs) of the same conductivity type which have a difference of threshold voltages corresponding to a difference of Fermi levels of gate electrodes thereof, both said gate electrodes of said first and second IGFETs being made of an identical semiconductor material and having a threshold determining portion of types selected from P, N and intrinsic, so as to provide said difference of Fermi levels thereof, the impurity concentrations of the semiconductor material of said P and N types being higher than 10^{18} cm^{-3} respectively, a gate of said first IGFET being used as an inverting input of said operational amplifier whilst a gate of said second IGFET is 35 used as a non-inverting input of said operational amplifier, an output terminal for delivering an output signal in response to a potential difference between said inverting and non-inverting inputs, and an input which is offset corresponding to said difference of threshold voltages:
a feedback connection means connected between said inverting input and output terminals of said operational amplifier for applying an output signal at said output terminal of the operational amplifier to said 40 inverting input terminal thereof; and
a reference connection means for applying a reference potential to said non-inverting input terminal of the operational amplifier, whereby the reference voltage based on the difference of said threshold voltages of said first and second insulated gate field-effect transistors is derived between said output terminal of said operational amplifier and said reference potential. 45
- 50 10. A reference voltage generating device constructed substantially as herein described with reference to and as shown in Figures 14, 15, 16, 17, 27, 28, 34, 35a, 39 and 56 of the accompanying drawings. 50
